EXECUTIVE SUMMARY

Marsh C.; McKenzie, A. (2018). Summary of input data for the 2017 PAU 5B stock assessment.

New Zealand Fisheries Assessment Report 2018/22. 82 p.

This document summarises the data inputs used in the 2017 stock assessment of blackfoot paua (*Haliotis iris*) around Stewart Island (PAU 5B). The eight sets of data available for the assessment were: (1) a standardised CPUE series based on catch effort landing return (CELR) data (2) a standardised CPUE series based on paua catch effort landing return (PCELR) data (3) a standardised CPUE series based on combined CELR and PCELR data (4) a standardised research diver survey index (RDSI) (5) a research diver survey proportions-at-lengths series (RDLF) (6) a commercial catch sampling length frequency series (CSLF) (7) tag-recapture length increment data and (8) maturity-at-length data. Catch history was an input to the model encompassing commercial, recreational, customary, and illegal catch.

A new standardisation was done for the CELR data using fishing duration as the measure of effort, the standardised CPUE series based on PCELR data was updated to the 2016–17 fishing year, and the combined CELR and PCELR data standardisation was updated to the 2016–17 fishing year. There had been no research diver survey since the last assessment, and therefore the same RDSI and RDLF were available for this assessment as in the last assessment. Scaled length frequency series from the commercial catch sampling were updated to the 2016–17 fishing year, where the catch samples stratified by area and numbers at length were scaled up to each landing and then to the stratum catch. New maturity-at-length data had been collected and were analysed for this assessment, but there were no new tag-recapture data since the last assessment.

1. INTRODUCTION

This document summarises the data inputs used in the 2017 stock assessment of the PAU 5B stock, Stewart Island. The work was conducted by NIWA under the Ministry for Primary Industries' contract PAU2017-01 Objective 1. A separate document details the stock assessment of PAU 5B (Marsh 2018). PAU 5B was last assessed in 2013 (Fu 2014, Fu et al. 2014), before that in 2007 (Breen & Smith 2008b), and in 2000 (Breen et al. 2000). The fishing year for paua is from 1 October to 30 September and in this document, we refer to fishing year by the year ending; thus we call the 1997–98 fishing year “1998”.

This report summarises the model input data available for PAU 5B up to the 2017 fishing year.

1. A standardised CPUE series covering 1990–2001 based on CELR data.
2. A standardised CPUE series covering 2002–2017 based on PCELR data.
3. A standardized CPUE series covering 1990–2017 based on combined CELR/PCELR data.
4. A standardised research diver survey index (RDSI).
5. A research diver survey proportions-at-lengths series (RDLF).
6. A commercial catch sampling length frequency series (CSLF).
7. Tag-recapture length increment data.
8. Maturity-at-length data.

Methodologies for the standardised CPUE indices are similar to those for recent assessments: PAU 5D (Fu et al. 2017), PAU 5A (Fu et al. 2015), and PAU 7 (Fu et al. 2016).

2. FISHERY DESCRIPTION

A list of common acronyms used in this document are given in Table 1.

The old PAU 5 Quota Management Area included the entire southern stock of paua from the Waitaki River mouth on the east coast of the South Island, south around to Awarua Point on the west coast including Stewart Island (Figure 1). The TACC allocation for PAU 5 was 445 t in 1986–87; quota appeals increased this to 492 t by 1991–92. For the 1992–93 fishing year quota holders agreed to a voluntary quota reduction which reduced the TACC to 443 t. In the 1995–96 fishing year, PAU 5 was divided into three substocks: PAU 5A, Fiordland; PAU 5B, Stewart Island; and PAU 5D, Southland/Otago (see Figure 1). It is widely considered that this led to a large redistribution of catch from Stewart Island to Fiordland and the Catlins/Otago coast (Elvy et al. 1997), but the extent to which this happened cannot be determined with certainty because the new stock boundaries are not aligned with the old statistical areas used to report catch and effort.

On 1 October 1999 a TAC of 155.98 t was set for PAU 5B, comprising a TACC of 143.98 t (a 5 t reduction) and customary and recreational allowances of 6 t each. Concerns of over-exploitation led to a series of management interventions to reduce the total allowable commercial catch (TACC). On 1 October, 1999, the industry agreed to shelve 25 t of quota in addition to the 5 t TACC reduction, resulting in an effective commercial catch limit of about 112 t. This shelving continued into 2000 at a level of about 22 t. In 2002, shelving was discontinued, and the TACC was set at 90 t, about 60% of the catch level in the 1995–96 fishing year. Since the 2007 fishing year the commercial fishers have

undertaken a number of other voluntary management initiatives including a steady increase in the minimum harvest size from the MLS (125 mm) to 138 mm for all statistical areas throughout PAU 5B.

Prior to the 1995–96 subdivision, estimated catch on the CELR forms was reported at the spatial scale of the General Statistical Areas (024 to 032) (Figure 1) This spatial resolution of catch reporting continued until 1 November 1997, after which time the new QMAs, PAU 5A, PAU5B and PAU5D were further subdivided into 17, 16, and 11 Paua Statistical Reporting Areas for PAU 5A, PAU 5B, and PAU 5D, respectively.. The spatial scale of reporting was further reduced from 1 October 2001, when the specific PCELR forms were adopted and it became mandatory to report catch and effort on the finer-spatial scale statistical zones originally developed for the New Zealand Paua Management Company’s voluntary logbook (Figures 2–3). A summary of the spatial resolution of reporting zones and research strata for PAU 5B are given in Tables 2–3 and Figure 4.

Table 1: A list of acronyms used throughout this document.

CELR	Catch Effort Landing Return
PCELR	Paua Catch Effort Landing Return
RDSI	Research diver survey index
CDLF	Commercial diver length frequency
RDLF	Research diver length frequency
PAU	Paua management
QMR	Quota Management Reports
MHR	Monthly Harvest Returns
SWFG	Shellfish Working Group
CV	Coefficient of variation
TAC	Total Allowable Catch
TACC	Total Allowable Commercial Catch
MLS	Minimum Legal Size
MHS	Minimum harvest size

Table 2: Summary of spatial and temporal resolution of catch effort data available for PAU 5B.

		QMA		Statistical Reporting Areas	
1986/87–1994/95	Oct 1995–present	1986/87–30 1997	Oct	Nov 1997–Sep 2001	Oct 2001–present

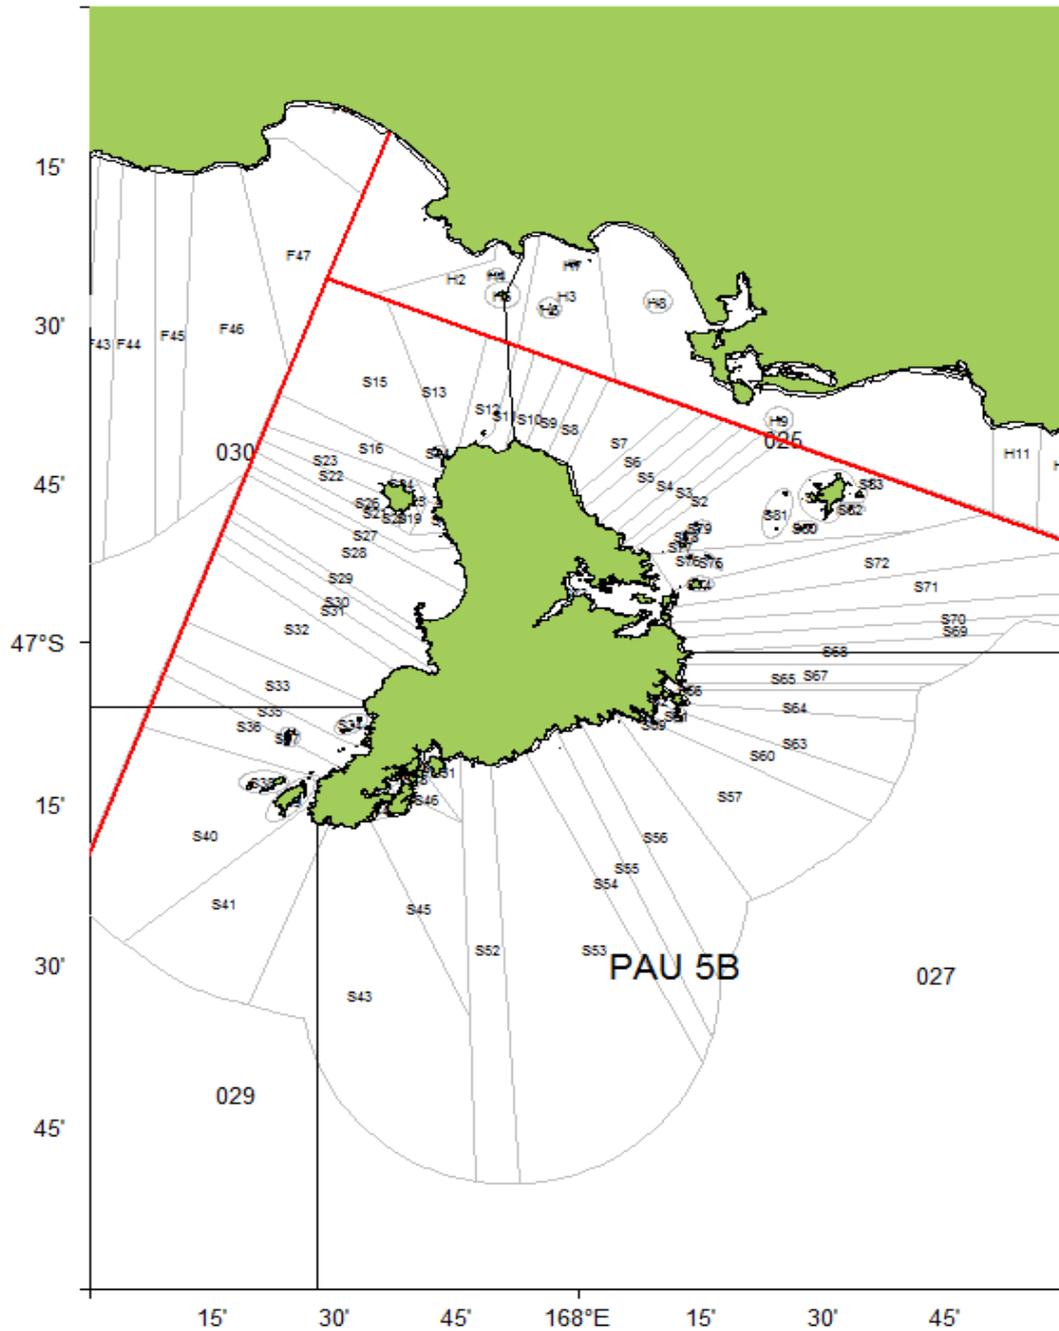

Figure 3: Map showing the location of fine scale Paua Statistical Areas within PAU 5B effective from 1 October 2001.

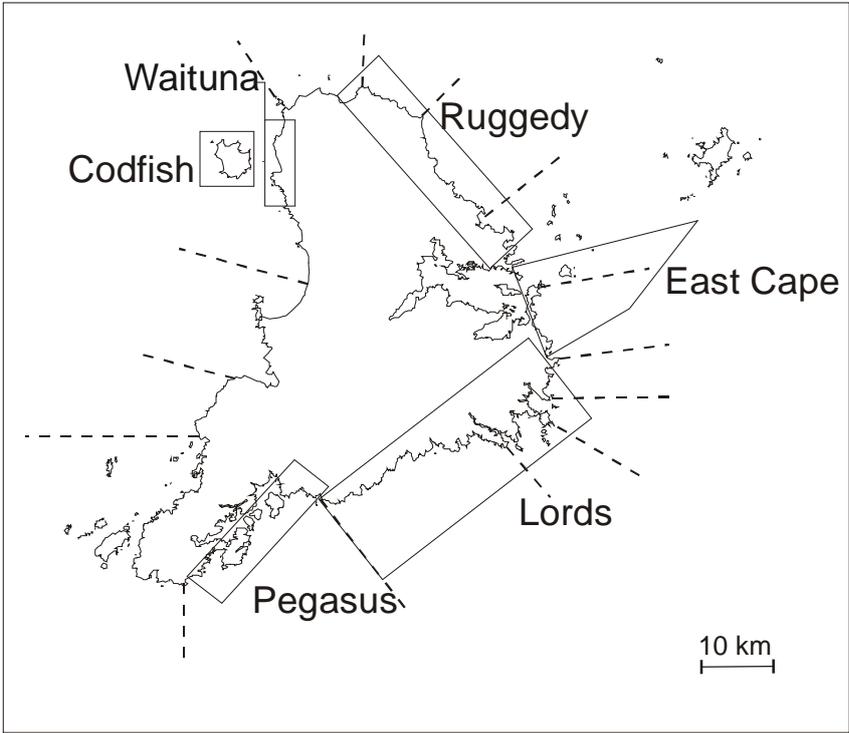

Figure 4: Map of research strata for PAU 5B stock.

3. CATCH HISTORY

3.1 Commercial catch

The subdivision of the PAU 5 stock and changes in the spatial scale of reporting commercial catch has led to complications in the allocation of catch data to the new QMAs. The historical catch series for the substocks within PAU 5 before 1995 cannot be determined with certainty, because some of the statistical areas used to report catch and effort straddle multiple stocks (e.g., Statistical Area 030 straddles PAU 5A, PAU 5B and PAU 5D - see Figure 1). Kendrick & Andrew (2000) described a method for estimating the pre-1995 catches from the substocks within PAU 5. The method was further explained by Breen & Smith (2008a), and was used to assemble the catch history for PAU 5A assessment in 2006 (Breen & Kim 2007), 2010 (Fu & McKenzie 2010) and 2014 (Fu et al. 2015) for the PAU 5B assessment in 2007 (Breen & Smith 2008b) and 2013 (Fu et al. 2014), and for the PAU 5D assessment in 2006 (Breen & Kim 2007), 2012 (Fu et al. 2013) and 2016 (Fu et al. 2017).

We repeated this procedure to calculate the catch history for PAU 5B. A constant proportion of 52% was applied to the Murray & Akroyd (1984) PAU 5 catch series to obtain catch estimates from 1974 to 1983. From 1983–84 to 1994–95, the annual proportion of catch for PAU 5B was firstly estimated, where 75% of the annual estimated catch in Statistical Areas 030 and 025 was assumed to have been taken from PAU 5B, and that proportion was applied to the QMR/MHR landings in PAU 5 to obtain the catch estimates. In the 2010 assessment for PAU 5A (Fu & McKenzie 2010), alternative assumptions were suggested by the SFWG concerning the proportion of catch in Statistical Area 030 that were taken from PAU 5A, PAU 5B, and PAU 5D between 1983–84 and 1995–96: (1) 18%, 75%, and 7% respectively, (2) 40%, 53%, and 7% respectively, and (3) 61%, 32%, and 7% respectively. These assumptions have been adopted here to obtain catch estimates for each of the substocks within PAU 5. Kendrick & Andrew (2000) also considered an alternative catch split of 67% to 33% between PAU 5B and PAU 5D for Statistical Area 025 between 1983–84 and 1995–96. This assumption was not used here because the difference it made to the catch estimates was insignificant. After the 1995 fishing year, the catch from Statistical Areas 025 and 030 are well determined (Figures 5–6)

Estimated commercial catch histories for PAU 5B are shown in Tables 4–5.

The estimated catches by Paua Statistical Area from the years of PCELR data are shown in Figure 7. Catches were taken throughout the stock and were widely distributed among subareas, with no signs of serial depletion in the last 17 years, at least at this scale.

The recorded resolution for the estimated catch and fishing duration for the PCELR data was low. About 70% of the catch was recorded as multiples of 50 kg, 25% of recorded fishing durations are multiples of one hour, and about 30% of fishing events the estimated catch was split equally amongst the divers (Figure 8). But there appeared to be no trend over time.

Table 4: TACCs and reported landings (kg) of puaa for PAU 5 and substocks PAU 5A, PAU 5B, and PAU 5D. PAU 5 was subdivided into PAU 5A, PAU 5B, and PAU 5D on 1 October 1995 and reported landings for these fish stocks are given separately from 1995–96.

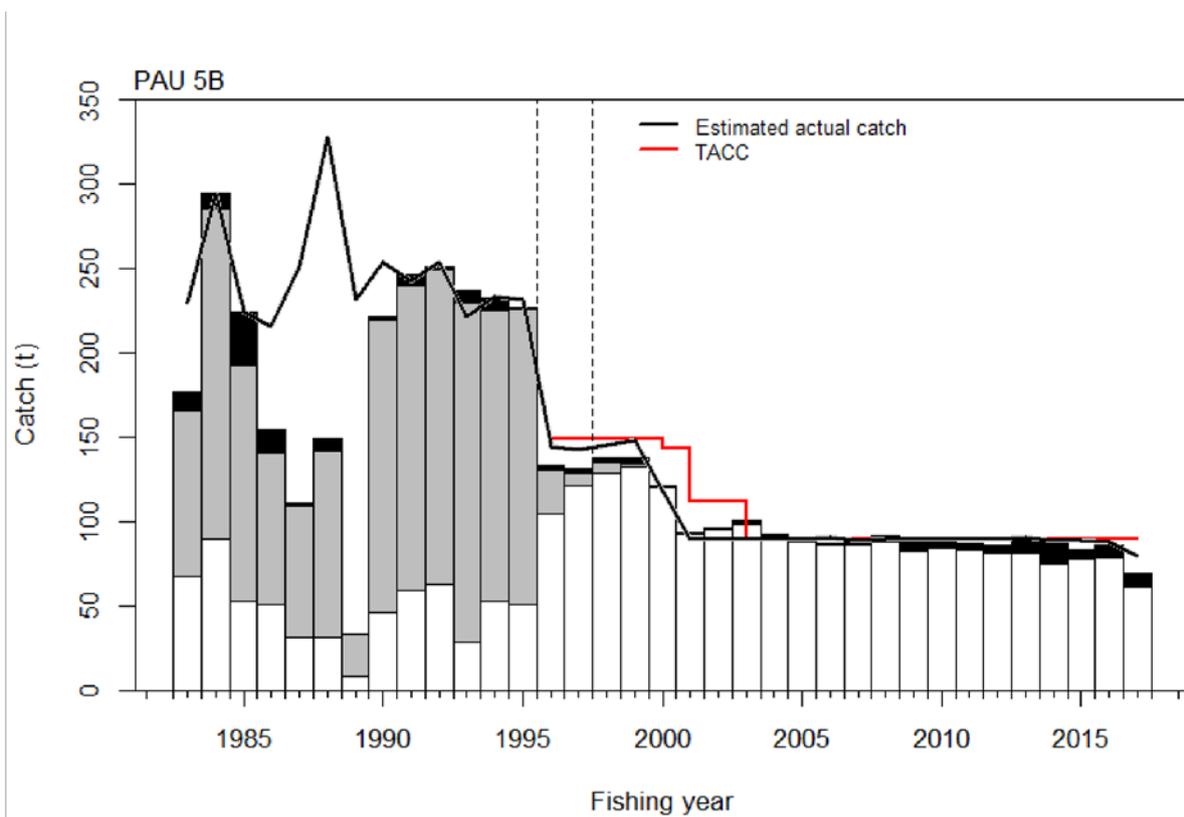

Figure 5: The estimated commercial catch history, TACC, and the FSU/CELR/PCELR catch (vertical bars) for fishing years 1983–2017 for PAU 5B. Black portion of the bar represents estimated catch removed through data grooming; grey represents the estimated catch from records reported to straddling Statistical Areas 025 and 030 but randomly allocated to PAU 5B.

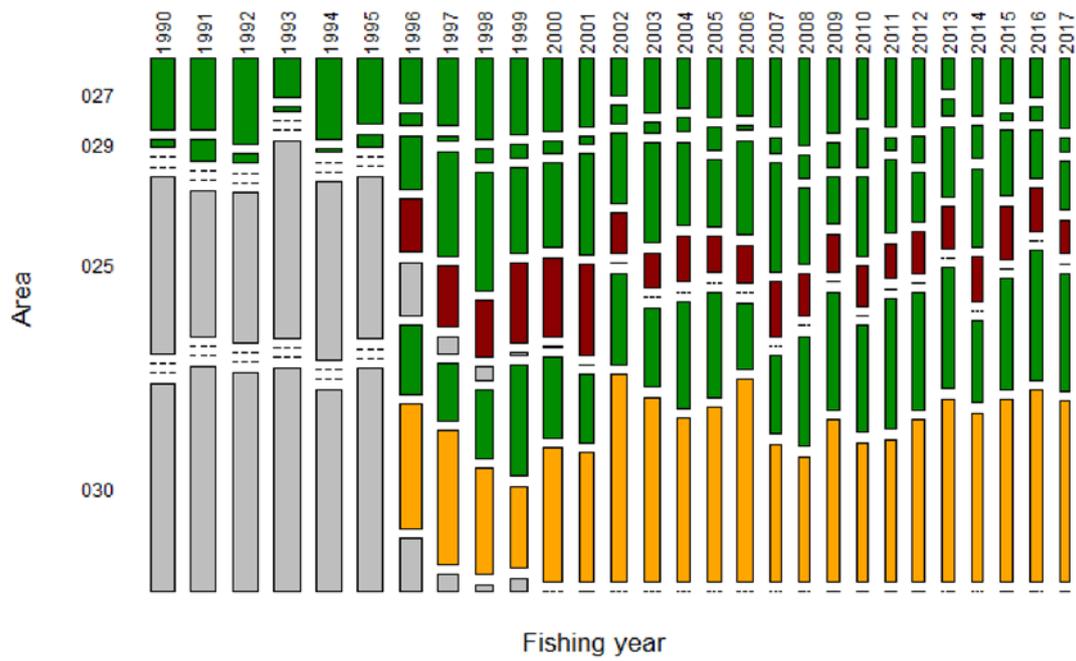

Figure 6: Estimated catch by statistical area and fishing year on the CELRs and PCELRs, 1990–2017. Green represents catch from within PAU 5B; red represents catch from Statistical Area 025 outside PAU 5B; orange represents catch from Statistical Area 030 outside PAU 5B; grey represents catch from areas with substock undetermined. The width of the bar is proportional to the total annual catch.

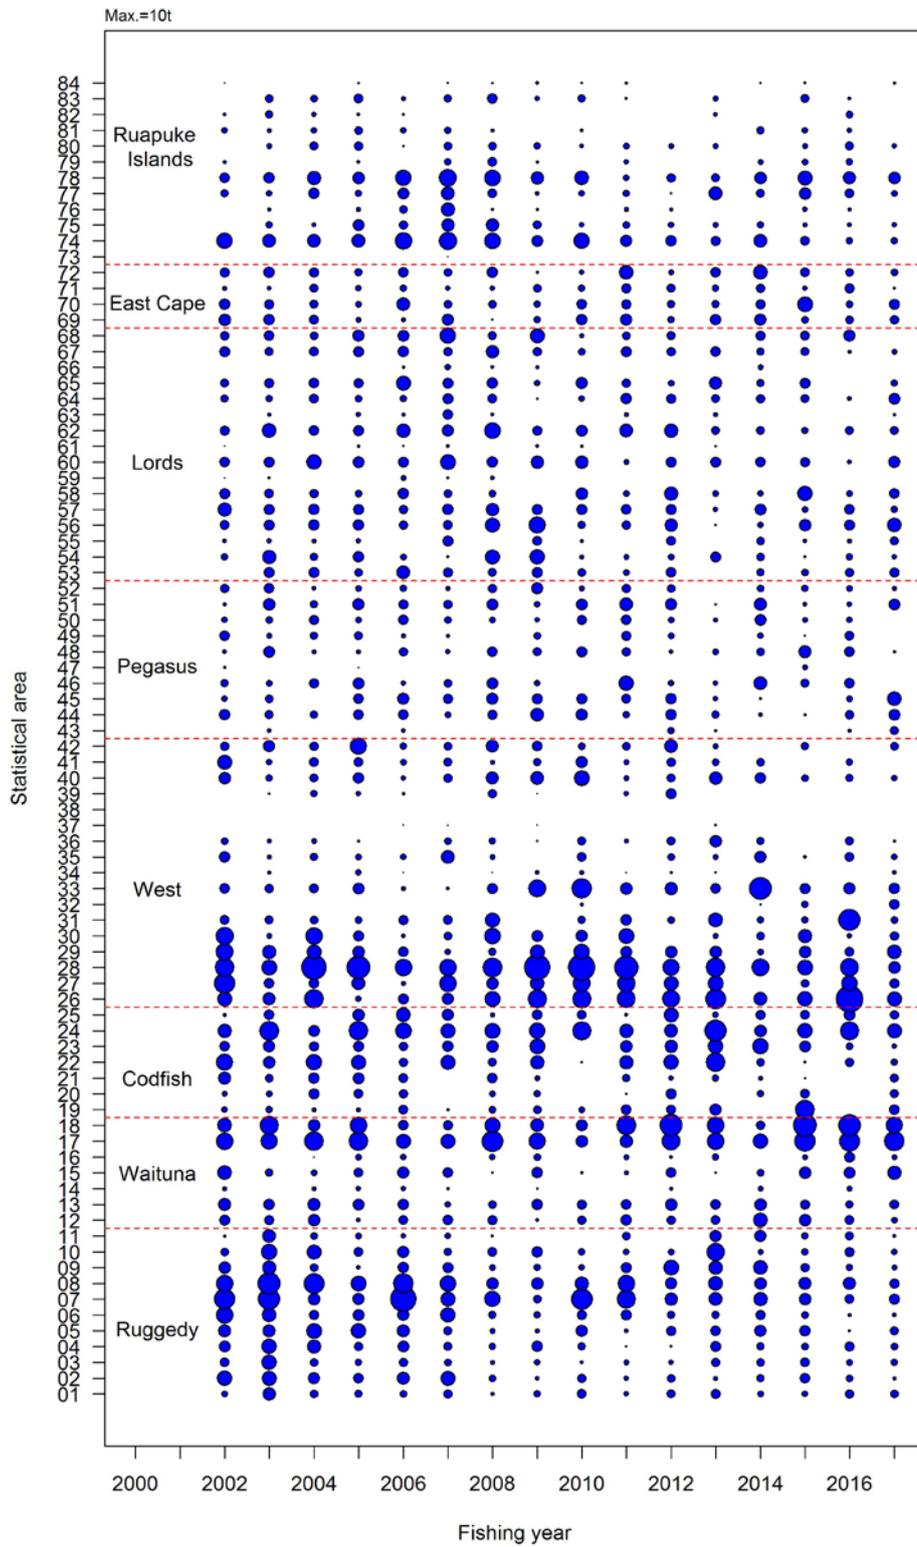

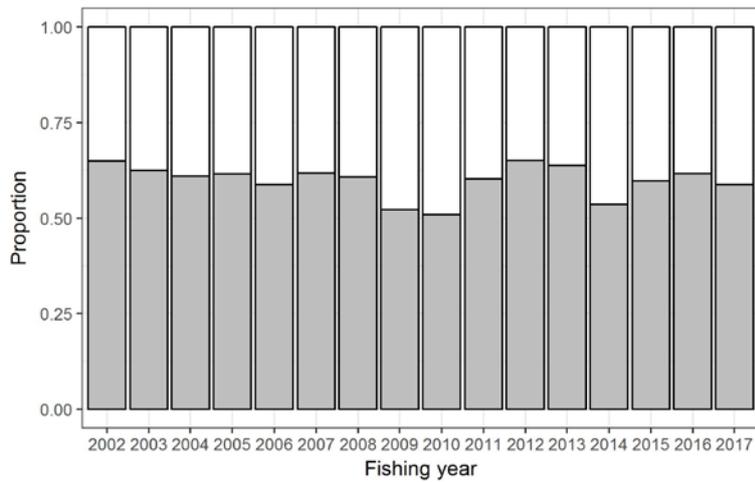

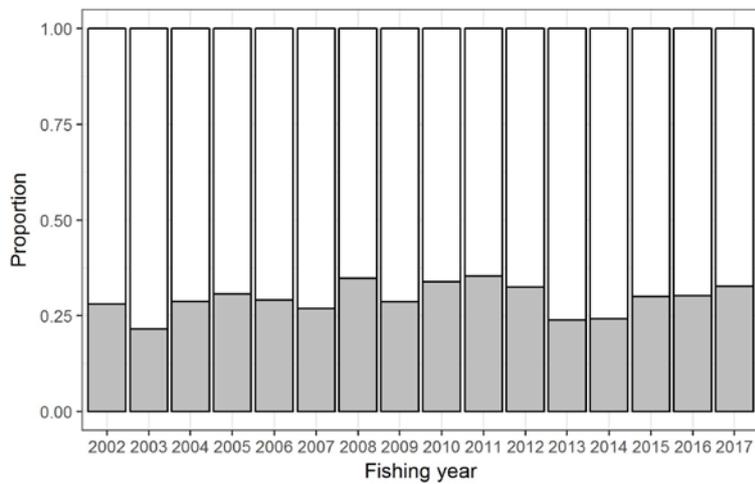

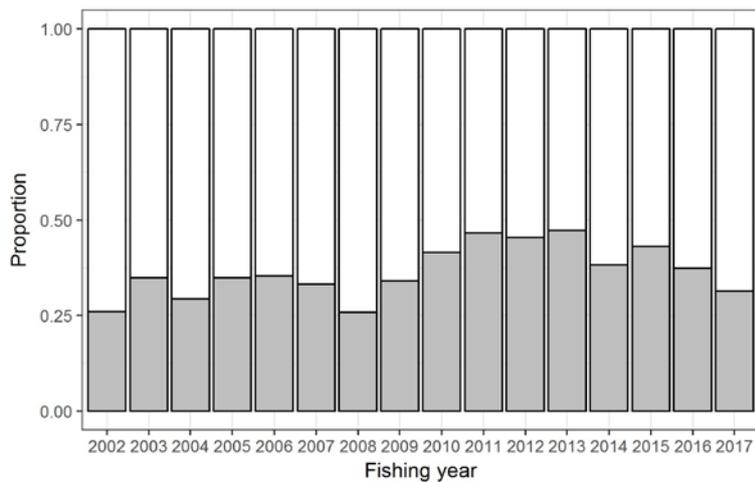

Figure 7: Annual estimated catch by Paua statistical area in PAU 5B for fishing years 2002–2017 from the PCELR forms. The size of the circle is proportional to the catch.

(a) Proportion of records that recorded estimated catch in a multiple of 50 kg.

(b) Proportion of records that recorded hours fished in an exact multiple of 1 hour.

(c) Proportion of fishing events where recorded estimated catch was equally split among divers.

Figure 8: Diagnostic of data resolution on the PCELR forms within PAU 5B: (a) multiples of 50 kg, (b) multiples of one hour, and (c) proportion of events equally split among divers.

3.2 Recreational catch

The 1996 and 1999–2000 National Recreational Fishing Surveys estimated that 37.1 t and 53.2 t respectively were taken from PAU 5 by recreational fisheries but with no substock breakdown. The Marine Recreational Fisheries Technical Working Group considered that some harvest estimates from the 1999–2000 and 2001–02 surveys for some fish stocks were unbelievably high. The Shellfish Fisheries Working Group (SFWG) examined estimates from national recreational surveys conducted in 1996 and 1999–2001, and following their discussions, the 2007 assessment for PAU 5B assumed that the 1974 recreational catch was 1 t, increasing linearly to 5 t in 2006. The New Zealand Recreational Marine Survey for 2011–12 estimated that the recreational harvest for PAU 5B was 0.82 t with a CV of 50% (Wynne-Jones et al. 2014). For this assessment, the SFWG agreed to assume that the recreational catch rose linearly from 1 t in 1974 to 5 t in 2006, and remained at 5 t between 2007 and 2017.

3.3 Customary catch

Reported annual customary catch is described in Table 6. In the assessment model estimated customary catch was assumed to be equal to 1 t from 1974–2017.

Table 6: Reported annual customary catch (in numbers) for PAU 5B under Te Runanga o Ngai Tahu. Assumed weight (kg) is derived assuming an average weight of 0.28 kg.

Year	Numbers harvested	Assumed weight (kg)
1999	90	25.2
2001	266	74.48
2002	460	128.8
2003	300	84
2004	510	142.8
2005	540	151.2
2006	260	72.8
2007	538	150.64

3.4 Illegal catch

Illegal catch was estimated by the Ministry of Fisheries to be 15 t (Breen & Smith 2008a), but “Compliance express extreme reservations about the accuracy of this figure.” For this assessment, the SFWG agreed to assume that illegal catch was zero before 1986, then rose linearly from 1 t in 1986 to 5 t in 2006, and remained constant at 5 t between 2007 and 2017.

Estimated commercial catch history including commercial, customary, recreational, and illegal catch for the 1974–2017 fishing years is shown in Figure 9.

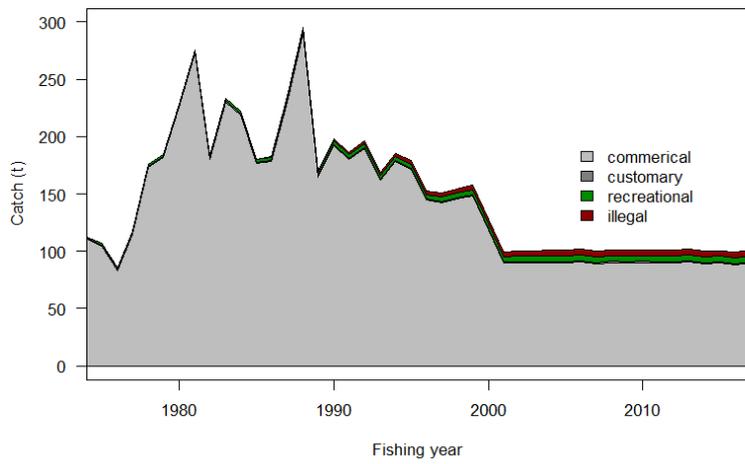

Figure 9: Estimated catch history including commercial, customary, recreational, and illegal catch 1974–2017 in PAU 5B, using assumption 3 for commercial catch between 1984-1995.

4. CPUE STANDARDISATIONS

4.1 Introduction

Earlier paua standardisations have included the Fisheries Statistics Unit (FSU) data covering the period from 1983–1988. However recent paua standardisations have excluded the FSU data because of problems regarding low coverage of the catch, lack of a vessel key, and undocumented corrections to the duration field (see for example Fu et al. 2016).

Data used in the standardisations included Catch Effort Landing Returns (CELR) covering 1990–2001, and Paua Catch Effort Landing Returns (PCELR) covering 2002–2017. It was decided by the Shellfish Working Group that duration (which changed over time), was a better measure of effort compared to the number of divers, and three standardisations were done:

1. CELR data (1990–2001)
2. PCELR data (2002–2016)
3. Combined CELR and PCELR data (1990–2016)

For the PAU 5B stock assessment, the combined CELR and PCELR data index was used with the CELR and PCELR indices examined as sensitivity analyses.

4.2 CELR data (1990–2001)

4.2.1 The CELR data standardisation approach

For the CELR data the Shellfish Working Group made decisions on the methodology:

1. NOT to randomly allocate catch-effort records from Statistical Areas 025 and 030 that overlap with PAU 5B, but are not entirely within it.
2. To use Fisher Identification Number (FIN) in standardisation procedures instead of vessel.
3. To filter the data to give a subset of the data for which the recorded fishing duration is less ambiguous, using the criteria: (i) just one diver, or (ii) fishing duration at least eight hours and at least two divers. Drop records with a fishing duration per diver of greater than 10 hours.
4. Not to put in a year:area interaction in the standardisations (to be used in the assessment), but to explore area differences in catch rates by doing separate standardisations where a year:area interaction is forced in at the start. For the CELR data the smallest possible areas sub-division is areas 025, 027, 029, 030.

Two differences from the previous PAU 5B CELR standardisation are:

1. Offering just fishing duration to the standardisation instead of both fishing duration and number of divers. This difference reflects the decision made for the previous paua standardisation in the PAU 5D area (Fu et al. 2017).

2. Including the non-filtered data as well, by scaling the recorded fishing duration for this by the number of divers. This was also done for the PAU 5A standardisation, for which the fishing duration characteristics looked similar (Fu et al. 2016).

Two sensitivity analyses were decided upon, these being based upon the review of the paua stock assessments (Appendix A):

1. Using records with just one diver. For one diver there were insufficient records to calculate a standardised index, so just a raw CPUE was calculated.
2. Using all the 025 and 030 data and calculating a standardised index. This was not recommended as a base standardised CPUE, but as a check to see how much difference it made.

4.2.2 The CELR data

The initial data set started with was CELR catch-effort records from PAU 5B. The Fisher Identification Number (FIN) and date were present for all records.

Some grooming of the catch-effort records was undertaken: records were retained only where paua was targeted by diving, and records were dropped with missing values for the estimated catch or number of divers (Table 7). This groomed data set has 3053 records (Table 8).

For the CELR data the fishing duration field was the total fishing duration for all divers. It has been noted in some past analyses that there is ambiguity as to what is recorded for fishing duration for the CELR data, because a mixture of total hours and per diver hours is put down, possibly attributable to the transition from the FSU forms to CELR forms.

For most trips the number of divers was three or less (Figure 10). One possible sign that fishing duration was incorrectly recorded as per diver, would be a decrease in the hours per diver as the number of divers go up. The hours per diver dropped by 25% going from one to two divers (Figure 11).

Another sign of incorrect recording for fishing duration would be a bimodal distribution for the fishing duration when there are two or more divers. What was seen for two divers was a single prominent mode that shifted further to the right compared to a single diver; and for three divers a smaller second mode to the right (Figure 12). This plot for the PAU 5B fishing duration distribution is similar to that for the nearby PAU 5A area (Figure 13), but somewhat different from PAU 5D where it is clearer that fishing duration was mostly recorded as hours per diver (Figure 14).

There is some ambiguity, but it appears that many of the records have fishing duration recorded on a hours per diver basis, with some recorded as total hours for divers. Hence it was decided to use the previous filtering criteria for PAU 5B (which retained records for which the total hours for divers was recorded), augmented with the procedure for PAU 5A where the rest of the data was also used by scaling the recorded fishing duration by the number of divers.

Table 7: Number of CELR records removed by fishing year, where the order of grooming is from top to bottom.

	1990	1991	1992	1993	1994	1995	1996	1997	1998	1999	2000	2001	Total
Not targeting paua	0	2	2	0	0	0	1	1	3	6	1	0	16
Catch missing	0	0	0	0	0	0	0	0	0	1	0	0	1
Number divers missing	0	1	0	0	0	0	5	3	1	5	1	0	16
Fishing duration missing	0	0	0	0	1	1	3	17	17	6	2	1	48
Method not diving	27	48	62	40	43	47	102	145	104	174	70	60	922

Table 8: Number of records after initial grooming. Fishing year is shown in an abbreviated form, for example 90 = 1990, 01 = 2001.

Fishing year	90	91	92	93	94	95	96	97	98	99	00	01	Total
After	128	129	165	73	144	179	286	344	400	371	435	399	3053

After scaling up fishing duration for non-subsetted data records, some final grooming was done in which records with NA for fishing duration were dropped (0 records), and a fishing duration per diver greater than 10 hours were dropped (7 records). The final subsetting retained 99.8% of the records from 1990–2001 (Table 9). Of the retained records 39% had one diver (Table 10).

For this data set the hours per diver increased by about half an hour from 1990–2001 (Figures 15–16). A raw CPUE using duration as the measure of effort gave a decline in catch rates that was slightly greater than if number of divers was used as the measure of effort (Figure 17). If all records were used then the CPUE decline was greater, compared to using records with just one diver (Figure 18).

One of the recommendations of the review, to reduce ambiguity in fishing duration, was to restrict records for the standardisation to just those with one diver. However, this restriction resulted in the number of records in each year becoming low, and this number would reduce by about another 75% when FIN subsetting for the standardisation was done (Table 11).

Table 9: Number of records in the dataset before and after final grooming. Fishing year is shown in an abbreviated form, for example 90 = 1990, 01 = 2001.

4.2.3 Standardised CELR

The initial set was that left after grooming and removing records for which the fishing duration per diver was greater than 10 hours (see the previous section).

FIN was used to subset out a core group of records, with the requirement that there be a minimum number of records per year for a FIN, for a minimum number of years. The criteria of a minimum of 7 records per year for a minimum of 2 years was chosen, thus retaining 84% of the catch over 1990–2001 (Figure 19). While 84% of the catch was retained overall, it was slightly less than this for some years (Figures 20–21). Number of days of effort retained after subsetting was 57 or more for every fishing year (Table 12, Figure 22). The number of FIN holders dropped from 84 to 29 under the subsetting criteria.

After subsetting there was good temporal overlap for FIN holder effort (Figures 23–24). Similarly, for temporal overlap in statistical area and month of the year (Figures 25–26).

CPUE was defined as daily catch. Year was forced into the model at the start and other predictor variables offered to the model were FIN, Statistical Area (025, 027, 029, 030), month, and total fishing duration (as a cubic polynomial).

The model explained 56% of the variability in CPUE with fishing duration (41%) explaining most of this followed by FIN (10%) (Table 13). The effects appeared plausible and the model diagnostics good (Figures 27–28). There was an apparent plateauing effect for the catch taken after a fishing duration of 15 hours, though for most of the records fishing duration was less than 15 hours (Figure 29). The standardised index showed a decline in catch rate that was steeper than the unstandardised index (Table 14, Figure 30).

4.2.4 Sensitivities to the base standardised CELR

Most of the catch and effort for the CPUE data were from areas 025, 027, and 030 with little from 029 (Tables 15–16). A standardisation with a year:area interaction forced into the model, showed similar trends from 1996–2001 for the separate areas, with differences between 027 and 029 before this (Figure 31).

In the base standardisation only records from 025 and 030 were used which were known to be in PAU 5B. In an alternative standardisation all records from 025 and 030 were used, resulting in a similar index to the base standardisation index (Figure 32).

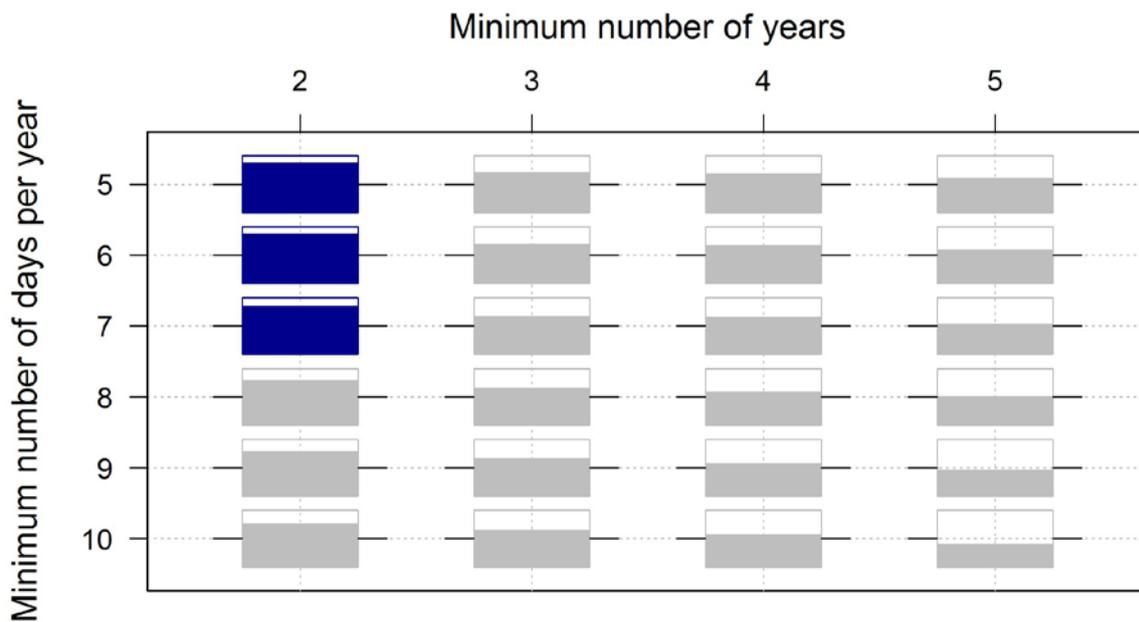

Figure 19: Proportion of the catch taken when subsetting the data by FIN with the requirement of a minimum number of daily records per year, for a minimum number of years. Each bar shows the percentage of the total catch from 1990–2001 retained under the criteria, where the horizontal line for each bar represents 50%. Bars with a fill colour of blue retain 80% or more of the catch, otherwise they are coloured grey.

4.3 PCELR data (2002–2017)

4.3.1 Introduction

For the PCELR data standardisation the same methodology was used as for the 2016 PAU 5D assessment (Fu et al. 2017). Some key aspects of this were:

1. To use Fisher Identification Number (FIN) in standardisation procedures instead of vessel.
2. Use FIN to subset out a core group of records.
3. Retain just the statistical areas and divers with ten or more records.
4. Not to put in a year:area interaction in the standardisations (to be used in the assessment), but to explore area differences in catch rates by doing separate standardisations where a year:area interaction is forced in at the start. For the PCELR data some natural divisions are based around the research strata (see Figure 4).

Further details of the standardisation methodology are in Section 4.3.3.

4.3.2 Data grooming and subsetting

The initial data set consisted of all records in which paua was targeted by diving. All records contained entries for FIN, fine scale statistical area, catch weight, fishing duration, and date. Records were removed from 2002 with no diver key (6 records). Some further grooming was done: 399 records were removed where no diving condition was recorded (Table 17).

Records were put in a daily format: total catch and dive time over a day for a diver (associated with a specific FIN, diving condition, and statistical area). CPUE was defined as the catch for a diver with fishing duration offered as a predictor in the model. Records with a CPUE greater than 200 kg/h were removed (0 records).

FIN was used to subset out a core group of records, with the requirement that there be a minimum number of records per year for a FIN, for a minimum number of years. The criteria of a minimum of 20 records per year for a minimum of 3 years was chosen, thus retaining 87% of the catch over 2002–2016 (Figures 33–35). The number of FIN holders dropped from 42 to 21 under these criteria. There was good overlap in effort for the FIN holders after subsetting (Figures 36–37). The number of records retained after subsetting was 209 or more for every fishing year (Table 18, Figure 38).

To ensure that there was enough data to estimate statistical area and diver effects in the standardisation, only those statistical areas and divers with 10 or more diver days were retained (see Table 18). This dropped the number of statistical areas from 83 to 76, and the number of divers from 479 to 86 (50% of divers have only one diving day - this was partly an artefact of the fact that a spelling mistake in the divers name looks like a completely new diver). There was very good temporal overlap for the other predictor variables statistical area, month, dive conditions, and diver (Figures 39–42).

Table 17: Number of records removed by fishing year where diving condition was not recorded (02 = 2012).

Fishing year	02	03	04	05	06	07	08	09	10	11	12	13	14	15	16	17	Total

4.3.3 Standardised PCELR

For the standardisation model CPUE (the dependent variable) was modelled as log(diver catch) with a normal error distribution. Fishing year was forced into the model at the start. Variables offered to the model were month, diver key, FIN, statistical area, duration (third degree polynomial), and diving condition. Following previous standardisations, no interaction of fishing year with area was entered into the model, because the stock assessment for PAU 5B is a single area model. However, a separate standardisation was also done where a year:area interaction was forced in at the start (using eight sub-areas based around the research strata).

Except for FIN, all variables were accepted into the model, which explained 81% of the variability in CPUE (Table 19). Most of the variability was explained by duration (66%) and diver (9%). The effects appeared plausible and the diagnostics were good (Figures 43–44). There was an apparent increasing effect for the catch taken after a fishing duration of 10 hours, although for most records fishing duration was less than 10 hours (Figure 45).

The standardised index showed an increase from 2002 to 2014, then a decline for two years followed by an increase in 2017 (Table 20, Figure 46).

Eight sub-areas for PAU 5B based on the research strata are given in Table 21. Each of these had a sizable number of records, allowing use in a standardisation with a year:area interaction, though the number was on the low side for East Cape and Pegasus where less of the catch was taken (Tables 22–23). Forcing a year:area interaction into the model gave similar indices for the different sub areas (Figure 47).

Table 19: Variables accepted into the PCELR standardisation model (1% additional deviance explained), and the order in which they were accepted into the model, their degrees of freedom (Df), and total variance explained (R-squared).

Predictors	Df	R-squared

4.4 Combined data (1990–2017)

4.4.1 The combined data set

For the years 1990–2001 the same data set was used as for the CELR standardisations. For the PCELR data the catch and fishing effort (both duration and number of divers) were collapsed down to a daily total for a given date, vessel, and large scale area (025, 027, 029, or 030). The collapsed PCELR data was then combined with the CELR data to give a dataset covering 1990–2017. All records with a fishing duration per diver greater than 10 hours were dropped (as was done for the CELR data) with the number of records remaining shown in Table 24 (the “before” column).

For the combined data set the daily hours per diver decreased from 1990 to 1995, then increased until about 2001, afterwards dropping until about 2012, then increasing again (Figures 48–49).

A raw CPUE based on either total daily duration or number of divers as the measure of effort showed a decrease until 2001, followed by an increase to 2009, then something of an irregular pattern (Figures 50–51).

Table 24: Number of records before and after FIN subsetting.

Fishing year	Before	After
1990	127	81
1991	129	74
1992	165	102
1993	73	57

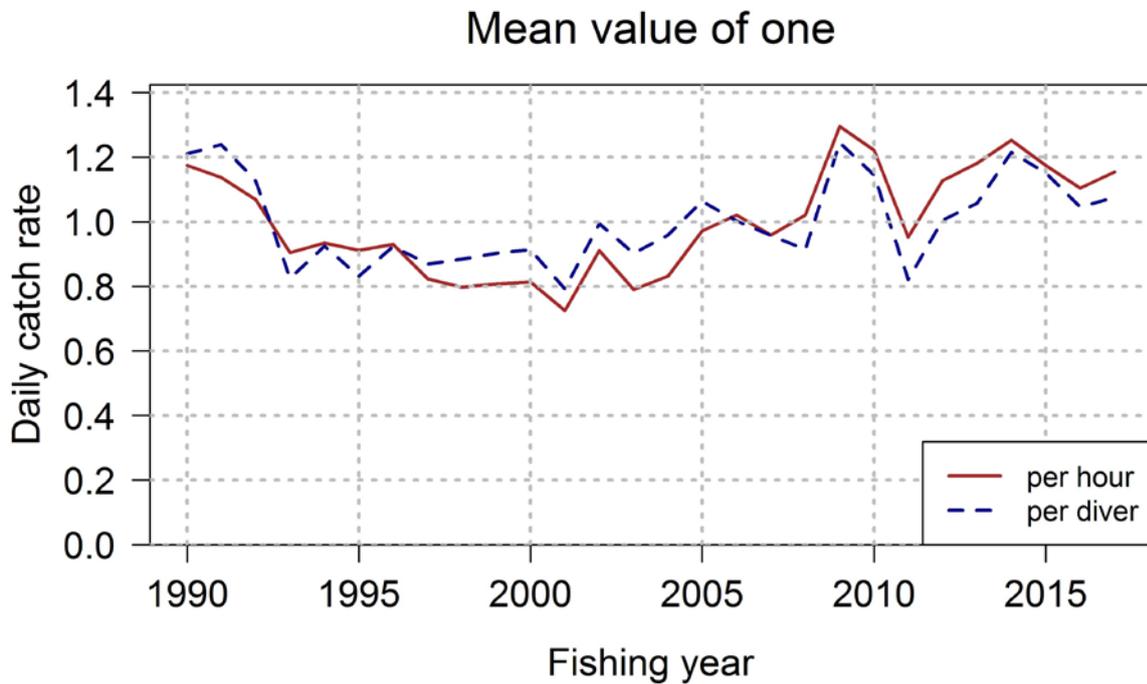

Figure 51: Geometric mean of the daily catch rate by year in the combined dataset where the plots are scaled so that they both have a mean value of one. Records with a fishing duration per diver greater than 10 hours are dropped.

4.4.2 The standardisation

FIN was used to subset out a core group of records, with the requirement that there be a minimum number of records per year for a FIN, for a minimum number of years. The criteria of a minimum of 10 records per year for a minimum of 2 years was chosen, thus retaining 88% of the catch over 1990–2017 (Figure 52). While 88% of the catch was retained overall, it was less than this for some years although always more than 40% (Figures 53–54). Number of days of effort retained after subsetting was 57 or more for every fishing year (see Table 24, Figure 55). The number of FIN holders dropped from 105 to 34 under the subsetting criteria.

After subsetting there was good temporal overlap for FIN holder effort (Figures 56–57). Similarly, for temporal overlap for area and month (Figures 58–59).

CPUE was defined as daily catch. Year was forced into the model at the start and other predictor variables offered to the model were FIN, month, and fishing duration (as a cubic polynomial).

The model explained 68% of the variability in CPUE with fishing duration (50%) explaining most of this followed by FIN (11%) (Table 25). The effects appeared plausible and the model diagnostics good (Figures 60–61). There was an apparent increasing effect for the catch taken after a fishing duration of 50 hours, though for most of the records fishing duration was less than this (Figure 62). The standardised index showed a decline from 1990–2001, followed by an increase until 2009, after which the index shows an irregular pattern (Table 26, Figure 63).

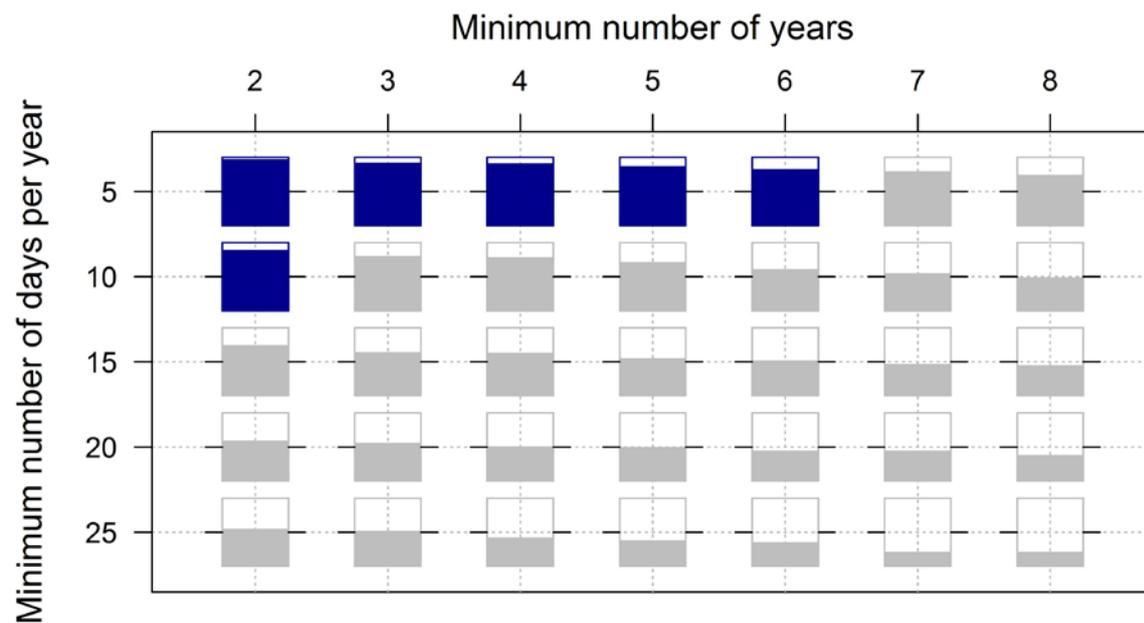

Figure 52: Proportion of the catch taken when subsetting the data by FIN with the requirement of a minimum number of daily records per year, for a minimum number of years. Each bar shows the percentage of the total catch from 1990–2017 retained under the criteria, where the horizontal line for each bar represents 50%. Bars with a fill colour of blue retain 80% or more of the catch, otherwise they are coloured grey.

5. COMMERCIAL CATCH LENGTH FREQUENCY (CSLF)

The paua catch sampling data comprise measurements of paua shells landed from the commercial catch (paua market sampling). Prior to 2006–07, the data were collected by NIWA and the length frequencies used were the basal length of the paua shell. This is the longest measurement along the anterior-posterior axis of the shell lip (as defined by the limit of the shell nacre when viewed with the shell upside down). It does not include the spire if it overhangs the base of the shell, or any encrusting organisms. Since 2006–07, the data have been collected by the Paua Industry Council and the industry now also measure and record overall length including the spire as well as basal length. Note that basal length differs from the measurement method used in the commercial fishery, in which the longest overall length is measured. For this reason, a small proportion of the market samples appear to be below the MLS of 125 mm.

A new extract of Catch Sampling Length Frequency (CSLF) data was made from the *market* database on 6 September 2017. This totalled 147 841 measurements from 1992–94 and 1998–2016. Deducing the statistical area of records prior to 2001–02 required some analysis as a variety of area codes were used.

The number of catch landings sampled per year ranged from 30 to 116 from 1992 to 2017 except in 1998 when there were only 9 samples taken (Table 27). Typically, over 4000 paua were measured each year. Between 2000 and 2006, about 20% of samples had no area recorded, because some operators refused to supply the information. Since 2002 most subareas have been consistently sampled and sampling coverage was reasonably adequate, although West appears to have small sample sizes for most years relative to its catch level and between 2011 and 2013 there seemed to be oversampling between the months of October and November (Table 28, Figures 64–65).

There appeared to be a temporal trend in length for the catch samples. The mean length of measured paua has increased since 2007 in most areas (Figures 66–67). This is due to the voluntary minimum harvest size (MHS) being increased by a total of 10 mm over a 5-year period in PAU 5B (it was increased to 127 mm in 2007, 131 mm in 2009, 133 mm in 2010, 135 mm in 2011, and 137 mm in 2015). There were also spatial variations in the mean length between subareas: paua sampled from Ruggedy were smaller than those sampled from Waituna and Pegasus. This spatial contrast was evident for both the early years from 2002 to 2006 and the recent years from 2007 to 2013 (see Figure 66).

Breen & Smith (2008a) weighted the length frequency by the ratio of area catch to the mean area catch within each year. Data without area information were not added to the weighted length frequency distribution. We adopted a modified approach to calculate the length frequency using NIWA's 'catch-at-age' software (Bull & Dunn 2002). Between 1992 and 2001, the catch samples were stratified using three spatial strata based on the General Statistical Areas: 025, 030, and 027/029. Between 2002 and 2017 the stratification was based on the research strata (see Figure 4). Strata in which there were no samples were combined with adjacent strata (i.e., Ruggedy was combined with Waituna in 2002 and 2005, Pegasus was combined with West in 2005, 2008, 2009 and 2014; East Cape was combined with Ruapuke in 2003 and 2007). The length frequencies of paua from each landing were scaled up to the landing weight, summed over landings in each stratum, and then scaled up to the total stratum catch to yield length frequencies by stratum and overall. The CV for each length class was computed using a bootstrapping routine: fish length records were resampled within each landing which was resampled within each stratum. For samples where landing weight was unknown the landing weight was assumed to be equal to the sample weight, calculated from the number of fish in the sample and mean fish weight. The final scaled length frequencies are shown in Figures 68–69.

Late in the assessment process commercial length frequency sample data were received for the 2017 fishing year, and it was suggested by the Shellfish Working Group to also include these data in the model run. These data had not been entered into the market database at the time the model was initially

run. The same stratification and bootstrapping procedure were applied to these new data (Figure 70) and the model re-run as a sensitivity.

Table 27: Number of landings sampled from the market shed sampling program by subarea and by fishing year.

Year	Number of landings sampled						Number of paua sampled

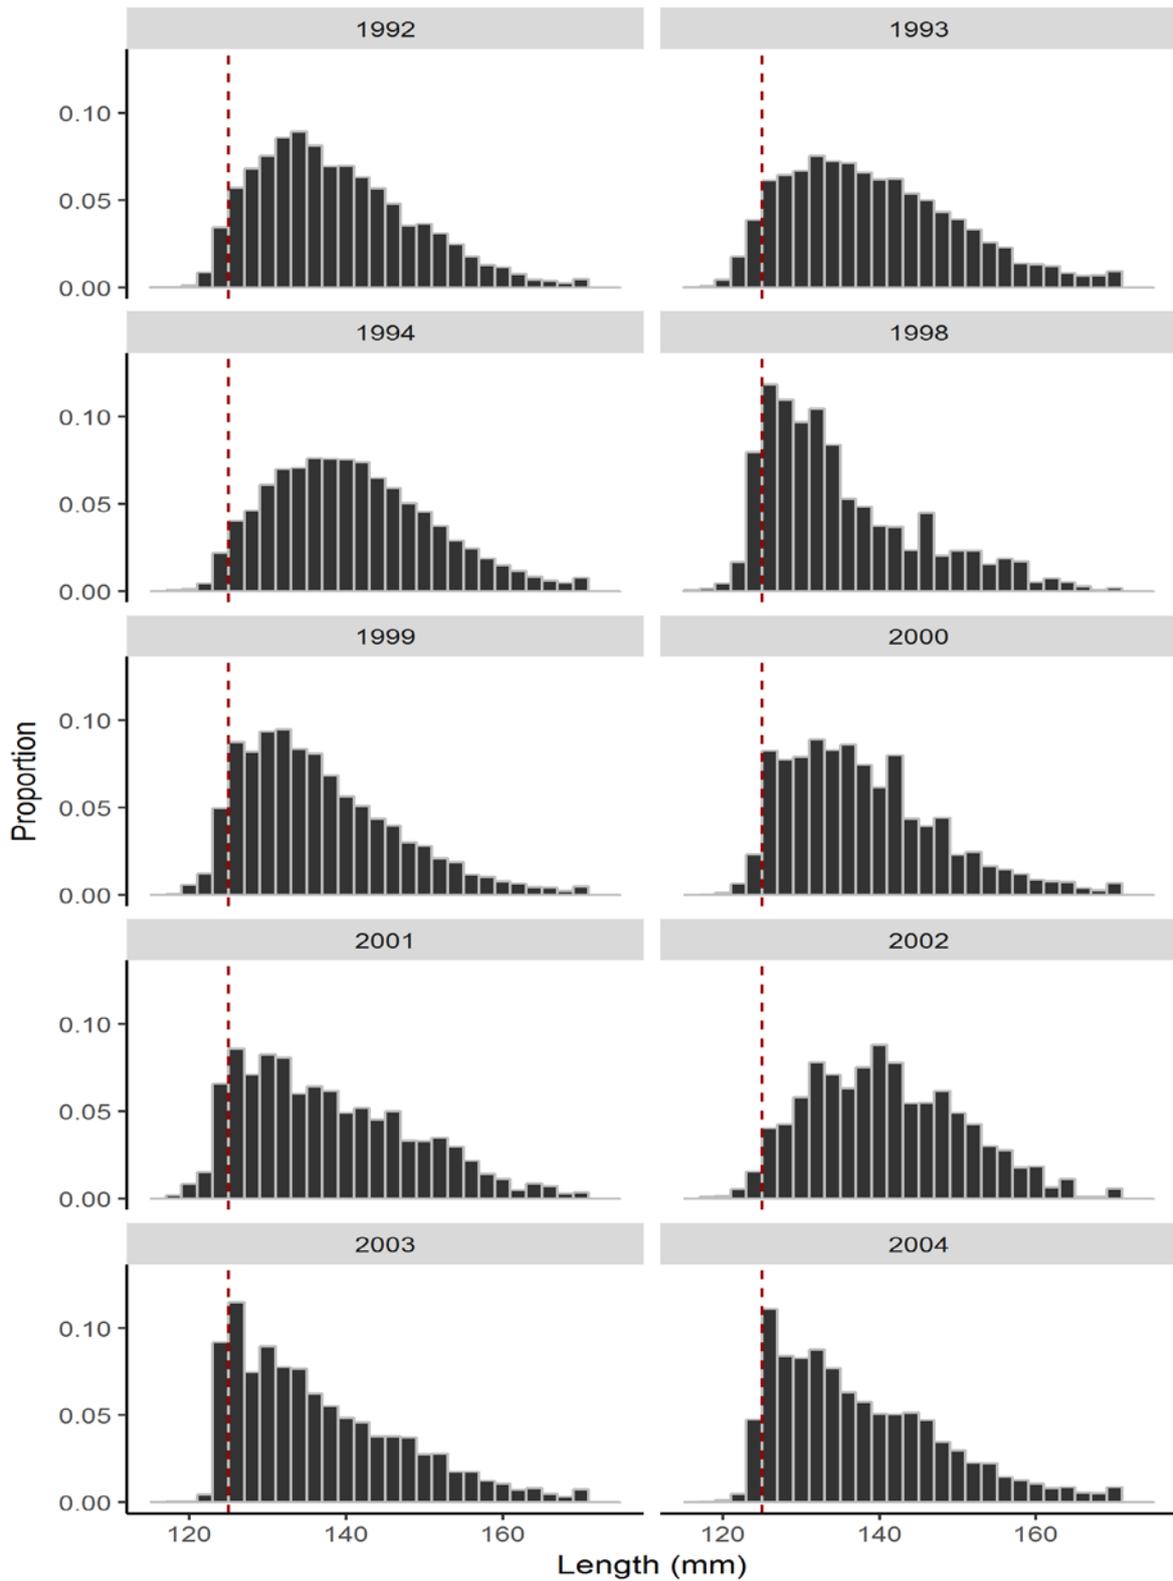

Figure 68: Scaled length frequency distributions for paua from commercial catch sampling for PAU 5B for fishing years 1992–1994, 1998–2004. The red dashed lines indicate the minimum legal size limit of 125 mm and the grey line indicated the voluntary minimum harvest size of 132 mm implemented more recently.

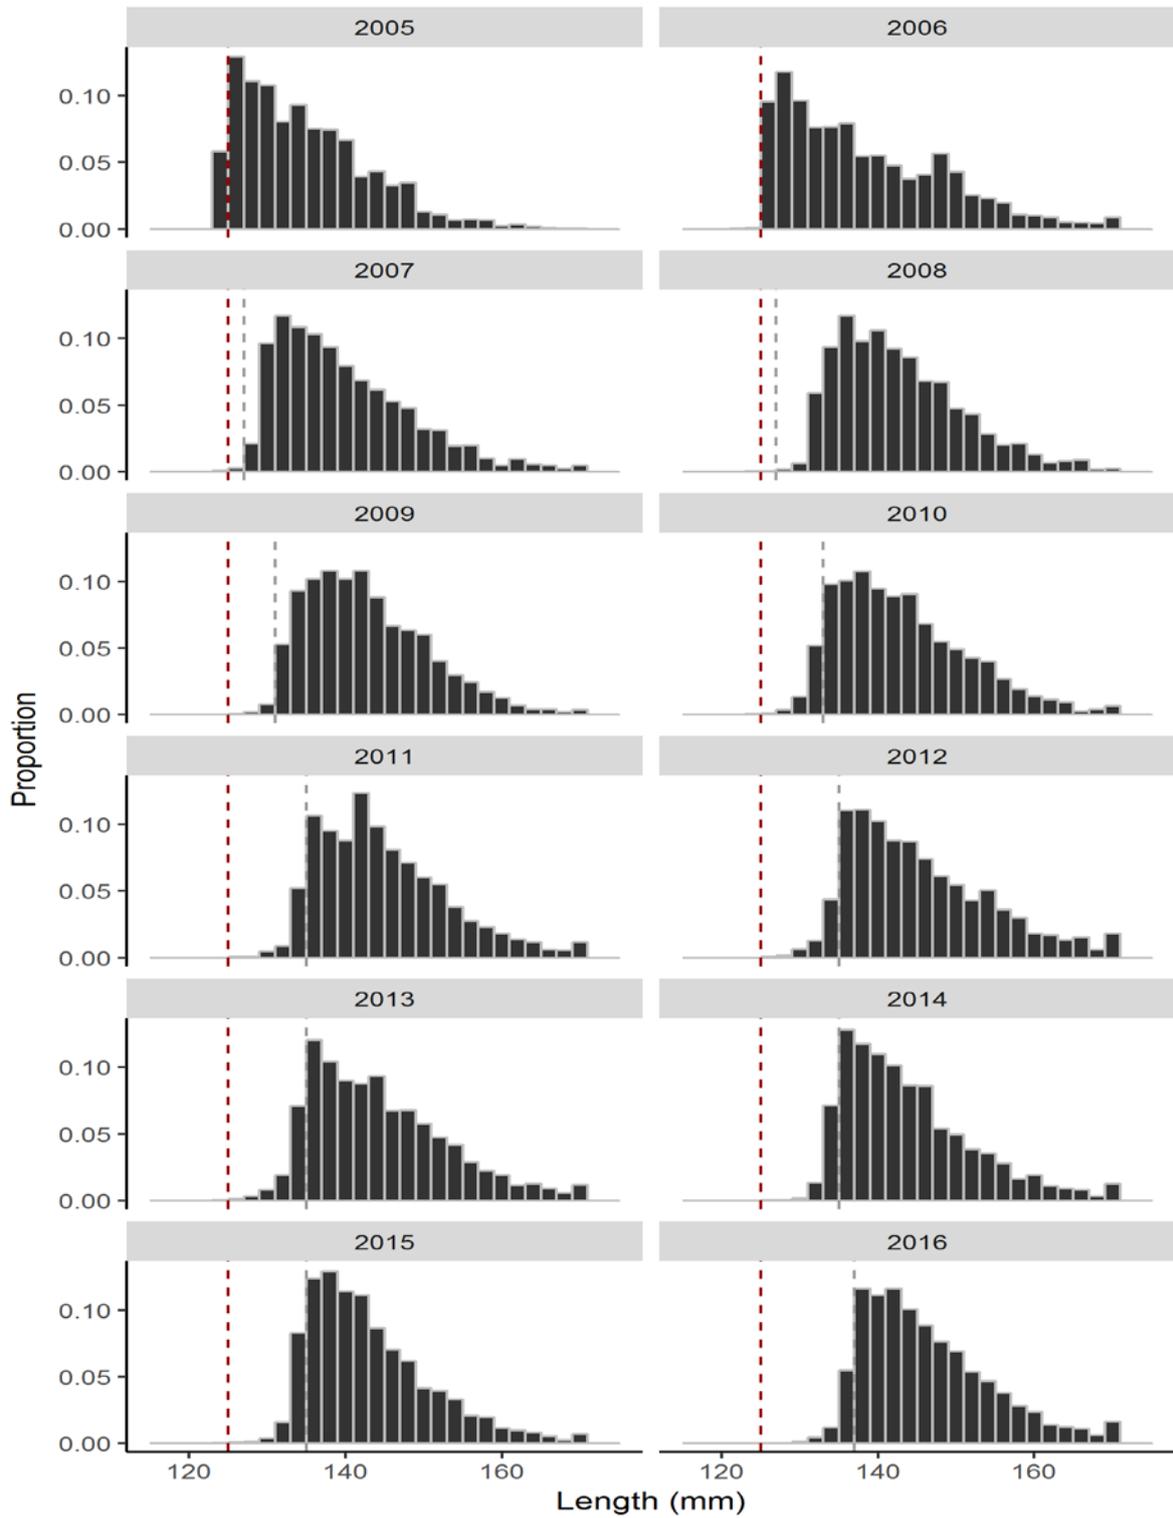

Figure 69: As in Figure 68 but for 2005–2016.

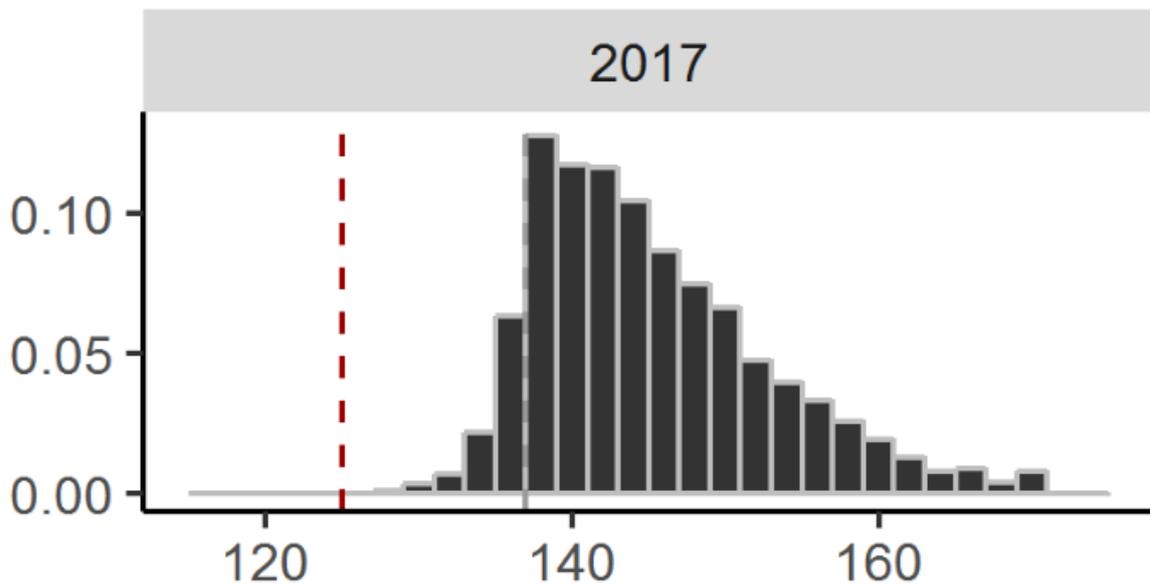

Figure 70: Scaled length frequency distributions for paua from commercial catch sampling for PAU 5B for the fishing year 2017. The red dashed lines indicate the minimum legal size limit of 125 mm and the grey line indicated the voluntary minimum harvest size of 138 mm implemented more recently.

6. RESEARCH DIVER SURVEY INDEX (RDSI)

Research diver surveys based on a timed-swim method developed by McShane (1994, 1995) and modified by Andrew et al. (2000a) have been conducted to assess the relative abundance of New Zealand paua stocks since 1991 (Andrew et al. 2000b, 2000c, 2002, Naylor & Kim 2004). Relative abundance indices estimated from the survey data (RDSI) have been routinely used in paua stock assessments in the past (Breen & Kim, 2007, McKenzie & Smith 2009, Breen & Smith 2008b). The previous stock assessment for PAU 5B used the RDSI developed from the survey data up to 2010 (Fu & McKenzie 2010). There have been no new surveys since the last assessment.

Concerns over the survey methodology and their usefulness in providing relative abundance indices led to several reviews. Andrew et al. (2002) recommended slight modifications which have been adopted and were subsequently reviewed by Hart (2005). Cordue (2009) conducted simulation studies and concluded that the diver-survey based on the timed swim approach is fundamentally flawed and is inadequate for providing relative abundance indices. More recently, Haist (2010) has suggested that the existing RDSI data are likely to be more useful at stratum level.

The calculation of the relative abundance indices from the RDSI data was re-worked for the last assessment (Fu 2014) to account for considerations of Haist (2010) and Cordue (2009), and is described in Fu et al. (2014). The RDSI relative abundance index is plotted in Figure 71.

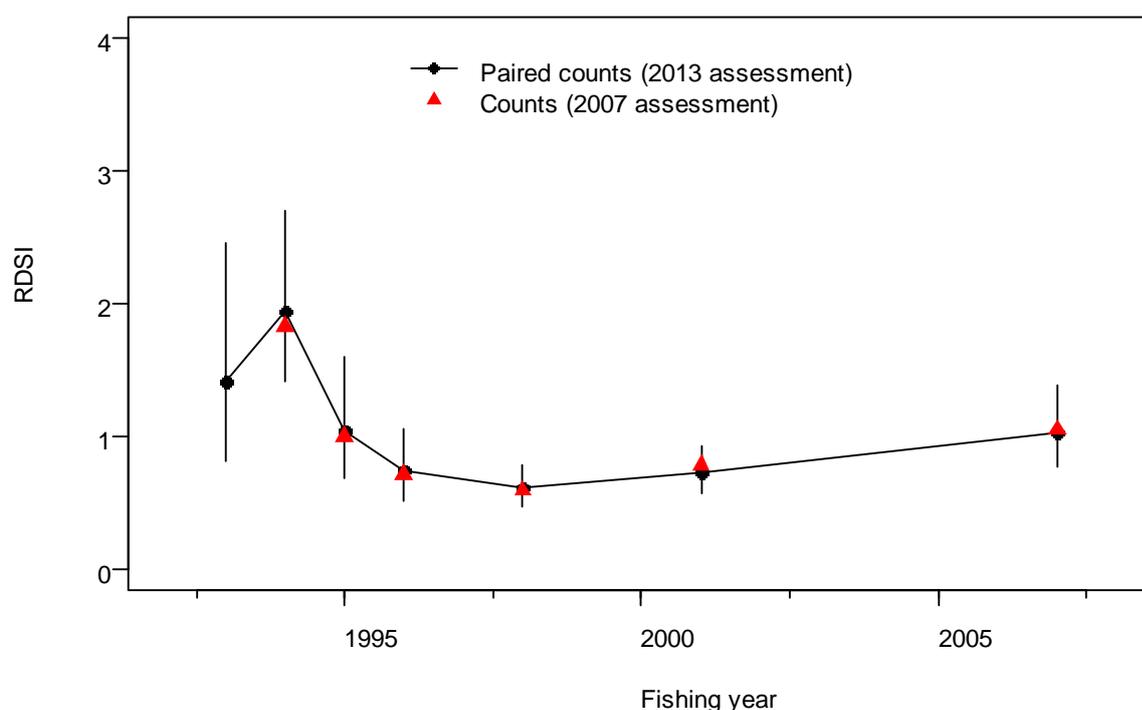

Figure 71: The standardised RDSI from the negative-binomial GLM models fitted to paired diver counts for surveys in PAU 5B. Also plotted are the estimated indices from the 2007 assessment in which individual diver counts were fitted by a Tweedie model (see Breen & Smith 2008a).

7. RESEARCH DIVER LENGTH FREQUENCY (RSLF)

Paua from the research diver survey were sampled to estimate the size composition at each site (Table 29). Since there have been no new surveys since the last assessment the RDLF has remained unchanged. The methodology for constructing these are described in Fu et al. (2014) and the scaled length frequency distributions are shown in Figure 72.

Table 29: Number of paua sampled from the research diver survey by stratum and fishing year.

	Ruggedy	Waituna	Codfish	West	Pegasus	Lords	East Cape
1982							93
1983	825

8. GROWTH TAG DATA AND GROWTH ESTIMATES

Tag and recapture experiments have been conducted at different times and at several sites in the PAU 5B (Breen & Smith 2008a) region. Growth data collected from these experiments were available from East Cape (n=116), Lords (n=52), Ruggedy (n=78), and Waituna (n=132). The growth dataset comprises of 333 records with initial tagged lengths ranging from 22 to 143 mm, time at liberty ranging from 214 to 364 days and annualised increments ranging from -2 to 54 mm. These data were incorporated into the PAU 5B assessment to estimate growth. No new tag recapture data since the last PAU 5B assessment have been collected.

Three models describing the rate of growth were available within the stock assessment model. With the linear growth model (Francis 1988) the expected annual growth increment for an individual of initial size L_k is

$$(1) \quad \Delta l_k = g_1 + (g_2 - g_1)(l_k - L_1)/(L_2 - L_1)$$

where g_1 and g_2 are the mean annual growth increments for paua with arbitrary lengths L_1 and L_2 .

For the exponential growth model the expected annual growth increment is:

$$(2) \quad \Delta l_k = g_1(g_2/g_1)^{(l_k - L_1)/(L_2 - L_1)}$$

where Δl_k is the expected increment for a paua of initial size l_k ; and g_1 and g_2 are the mean annual growth increments for paua with arbitrary lengths L_1 and L_2 .

With the inverse logistic model (Haddon et al. 2008) the expected annual growth increment for a paua of initial size l_k is:

$$(3) \quad \Delta l_k = \frac{\Delta_{max}}{1 + \exp(\ln(19) \left(\frac{l_k - l_{50}^g}{l_{95}^g - l_{50}^g} \right))}$$

where Δ_{max} is the maximum growth increment l_{50}^g is the length at which the annual increment is half the maximum and l_{95}^g is the length at which the annual increment is 95% of the maximum.

The assessment model included the growth-increment data as an observational dataset and estimated the growth parameters within the model. Therefore, the estimated growth parameters were also dependent upon other observations included within the model (e.g. commercial length frequency data). Below we present a simple analysis of the tag-recapture data using the three growth models described above. Note that this was a separate exercise outside the assessment model, and the estimates were solely based on the tag-recapture data. Those estimates were likely to be different to the growth parameters estimated from the assessment model.

The parameters were estimated using maximum likelihood as defined in Dunn (2007) in this preliminary analysis. Variation in growth was assumed normally distributed with $\sigma^{\Delta l_k} = \max(a(\Delta l_k)^\beta, \sigma_{min})$, where Δl_k is the expected at length l_k truncated at zero, σ_{min} is the minimum standard deviation assuming fixed at 1 mm and $a(\Delta l_k)^\beta$ is the standard deviation of growth at length l_k (if β is fixed at 1 α will be the coefficient of variation and if β is fixed at 0 α will be the standard deviation). The likelihood function maximised was:

$$L_i(\Delta l_i, \sigma^{\Delta l_i}, \sigma_E) = \frac{1}{\sigma_E} \phi\left(\frac{y_i}{\sigma_E}\right) \Phi\left(-\frac{\Delta l_i}{\sigma^{\Delta l_i}}\right) + \frac{1}{\sqrt{\sigma^{\Delta l_i^2} + \sigma_E^2}} \phi\left(\frac{y_i - \Delta l_i}{\sqrt{\sigma^{\Delta l_i^2} + \sigma_E^2}}\right) \Phi\left(\frac{\sigma^{\Delta l_i^2} y_i - \sigma_E^2 \Delta l_i}{\sqrt{\sigma^{\Delta l_i^2} \sigma_E^2 (\sigma^{\Delta l_i^2} + \sigma_E^2)}}\right)$$

where y_i is the measured growth increment for the i^{th} paua; Δl_i and $\sigma^{\Delta l_i}$ are the expected growth (truncated at zero to exclude the possibility of negative growth) and standard deviation respectively; σ_E is the standard deviation of measurement error (assumed to be normally distributed with mean zero); and ϕ and Φ are the standard normal probability density function and cumulative density functions respectively. The measurement error σ_E was assumed to be known as 1 mm.

The inverse logistic model had the best fit (Table 30), for which Figure 73 shows the fit and residual. The residual patterns suggest there was spatial variation in growth. The models were fit to the complete dataset and a subset that only included initial tag size greater than 70 mm. A customary practice in the paua stock assessment is to begin modelling the stock from 70 mm at length, thus rendering smaller tag recapture data redundant.

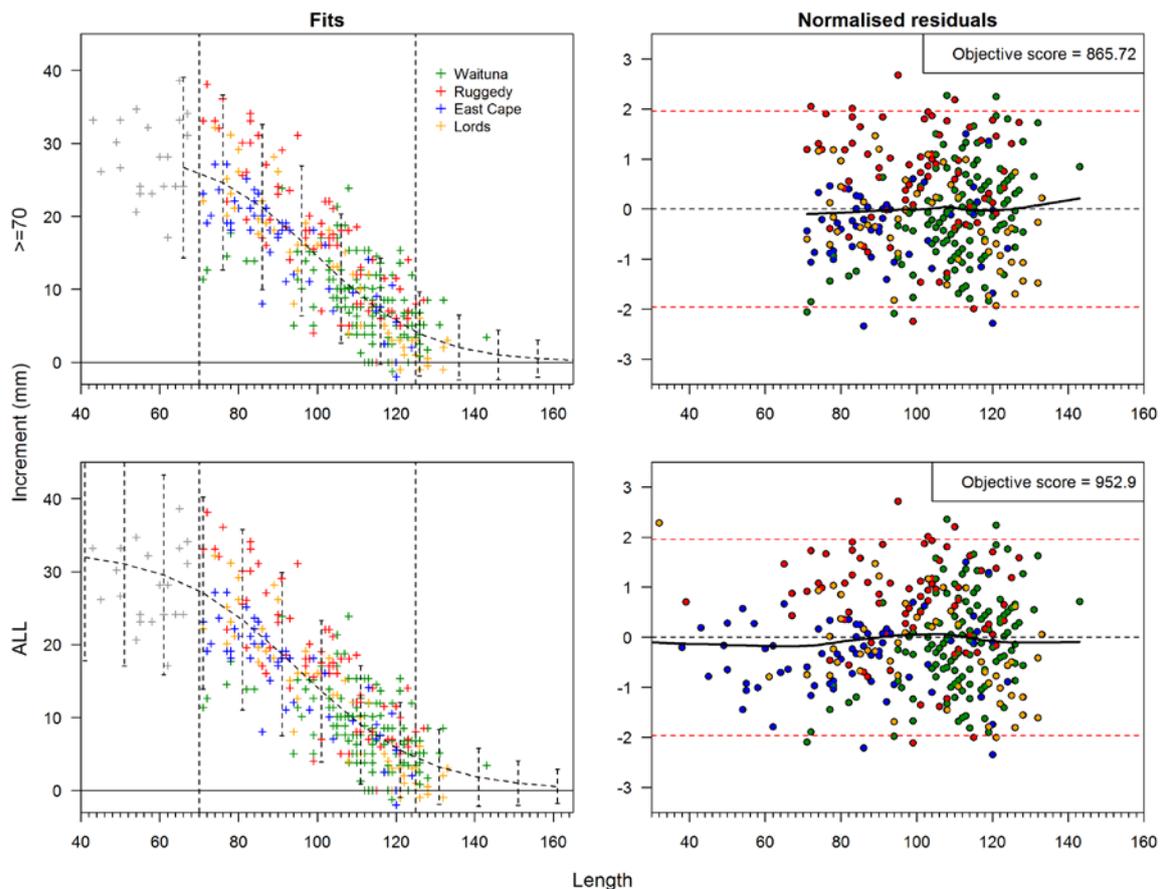

Figure 73: The fit and residuals for the inverse logistic model.

Table 30: Negative log likelihood values from the maximum likelihood routines for all growth models and across all data and for a subset of data where the model was only fit to data greater than 70 mm.

	All data	data \geq 70mm
Linear	880.4	963.83
Exponential	866.27	999.28
Inverse logistic	865.72	952.9

9. MATURITY

Maturity data has been collected from several sites in the PAU 5B area since 1994 (Table 31). Figure 74 shows the spatial distribution of sampling. Latitude and longitude coordinates were available after 2014; before that only the research stratum was available. Length-at-maturity is described by the logistic ogive in the stock assessment model and is estimated internally within the model. We explored the data in a similar fashion to the growth data, in which a preliminary analysis was done fitting a generalised linear model with a logit link. For this analysis some sites were grouped together so that there was a large enough sample size to get an estimate of the key parameters: (i) Codfish, Waituna, and East Cape (2) Lords and Pegasus.

There was variability in maturity over time and across different sites, with the a_{50} parameter varying between 78 cm and 104 cm (Table 32). The combined data estimates of maturity suggested that 50% of fish at 95.8 cm would be mature, and by 116 cm the probability of being mature is about 95% (Figure 75).

Table 31: Number of pua sampled for maturation state in the PAU 5B stock by area and year.

	1994	1995	2006	2007	2014	2017

APPENDIX A

In March 2015 an expert panel reviewed the New Zealand paua stock assessment models and associated data collection programmes (Butterworth et al. 2015). Recommendation twenty one from the review concerned paua CPUE standardisations and states the following:

“Robustness to the CPUE standardisation assumptions should be fully investigated by developing alternative CPUE series to test in model sensitivity runs. Alternative series potentially include: PCELR data collapsed to the CELR format to form a single CPUE series; standardising CELR data by diver day instead of by diver hour; and for PAU 5B, including data from all Statistical Area 25 and 30 observations into the CELR standardisation. Unless there is clearly no effect of the alternative standardisation approach, the alternative CPUE series should be fitted in the assessment model as sensitivities”.

Rationale: *The CPUE indices have a large effect on model estimates of abundance, in particular the recent trends in abundance. As such, model sensitivity to alternative CPUE indices will likely show more variability in the estimates of recent trends than other sensitivity runs.*

For the PAU 5B CELR standardisation, virtually all of the Area 25 and 30 catch-effort data for 1990-1995 are excluded from the standardisation because these areas are partially outside of PAU 5B. Given that Area 25/30 represents over half of the PAU 5B catch, if CPUE trends in these areas differ from those of Areas 27/28, the standardised CPUE will not reflect abundance trends. An approach to check for this would be to conduct a CELR standardisation that includes all Area 25 and Area 30 catch-effort records (approximately 75% of the catch from these areas is attributed to PAU 5B).

The selection of data records for the CELR standardisation (using diver hours as the fishing duration measure) may introduce bias. Records are selected where the number of divers is 1, or the number of divers is 2 or greater and the number of hours fished is 8 or greater. The data for single divers often have median dive times of about 4 hours, which suggests that many records with legitimate dive times (i.e. 2 divers and less than 8 hours fished) would be eliminated. This is a problem, in terms of bias, only if catch rates for short duration days differ from long duration days. The only way to ensure unbiased data to evaluate if dive hours per day has changed over time, or if there is correlation between catch rates and fishing hours/day, is to restrict the data set to records that represent a single diver. Any other process will retain some erroneous records and remove some correct records.
