Objectives

The primary objective of the targeted marine surveillance programme is:

- To detect incursions of the target organisms at the identified locations.

The secondary objectives of the targeted marine surveillance programme are:

- To detect incursions of non-target non-indigenous or cryptogenic species not previously recorded in New Zealand.
- To detect incursions of established non-indigenous or cryptogenic species which are exhibiting invasive characteristics (i.e. range extensions of established organisms).

The targeted marine surveillance programme must meet the primary objective. Surveillance should be designed and undertaken with the purpose of maximising the likelihood of successful “containment” of the incursion through providing sufficient probability of detection to maximise the range of management options available, i.e. vector management and local control etc. The secondary objectives should be considered when designing and undertaking the surveillance programme to increase the likelihood that these will be achieved within the existing design or through minor additions/modifications to this design (these will need to be clearly identified and approved).

TARGET SPECIES

MAF Biosecurity New Zealand has currently identified seven marine organisms which are listed on the unwanted organisms register. These are the:

1. Clubbed tunicate, *Styela clava*
2. Northern Pacific seastar, *Asterias amurensis*
3. European shore crab, *Carcinus maenas*
4. Aquarium weed, *Caulerpa taxifolia*
5. Mediterranean fanworm, *Sabella spallanzanii*
6. Chinese mitten crab, *Eriocheir sinensis*
7. Asian Clam, *Potamocorbula amurensis*

An additional three organisms have been identified that are not currently listed as unwanted organisms and are currently known to be established in New Zealand’s coastal waters. Knowledge of changes in the distribution of these organisms is of interest for current and potential future management purposes. Within the survey design for the primary organisms, opportunities should be explored for detecting these secondary organisms. These organisms include:

8. Asian Date Mussel, *Musculista senhousia*
9. *Eudistoma elongatum*
10. *Didemnum* sp.¹

Note: the target organism list may be subject to change by MAFBNZ during the course of the surveillance programmes. Inclusion of additional target species may be considered by MAFBNZ.

¹ Representative samples of *Didemnum* species will be collected and submitted to MITS for future reference. Further identification to species will not be undertaken as part of this programme. The samples will be made available by MAF where these are required for approved purposes.

Stakeholder engagement and governance

IDENTIFYING RESPONSIBILITIES WITHIN THE SURVEILLANCE AREA

Stakeholder groups with jurisdiction or responsibility within the surveillance location are listed in Table 1.

Table 1 List of stakeholder groups with jurisdiction or responsibility within the surveillance location.

Node/Facility	Responsible group	Contact name
Commercial trading port	Port Marlborough New Zealand Ltd (03 520 3399)	Steve Redshaw (Shipping and Security Coordinator)
Commercial trading port	Port Marlborough New Zealand Ltd (03 520 3399)	Carmen Gimple (Port Operations and Commercial)
Marinas	Port Marlborough New Zealand Ltd (03 520 3399)	Jeanine Paul (Marinas Manager)
Marinas	Port Marlborough New Zealand Ltd (03 520 3399)	Steve McKeown (Marinas Operations Manager)
Marinas	Port Marlborough New Zealand Ltd	Waikawa: Brian Carver (Manager, 03 520 3395)
Marinas	Port Marlborough New Zealand Ltd	Picton: Dave Mahony (Manager, 03 520 3390)
Marinas	Port Marlborough New Zealand Ltd	Havelock: Geoff Hayter (Manager, 03 574 2236)
Local authority biosecurity	Marlborough District Council (03 520 7400)	Keith Heather (Resource Management Officer)
Local authority harbour master	Marlborough District Council (03 520 7400)	Alex van Wijngaarden (Harbour Master)
Fisheries regulator	Ministry of Fisheries (03 548 1069)	Geoff Clarke (Compliance Officer)
Private wharf operator/user	Sanfords Havelock (03 574 2021)	Dave Herbert (Operations Manager)t

OBTAINING PERMITS TO CONDUCT SURVEILLANCE FIELDWORK

Contact has been made with all the organisations listed in Table 1 during previous surveys of the port and a letter (see Appendix 1) has been sent to each summarising the purpose of the surveillance programme and, where required, requesting permission to sample. To date, permission has been granted whenever requested and all stakeholders have indicated that their cooperation will continue in the future.

GOVERNANCE

MAF Biosecurity New Zealand

MAF Biosecurity New Zealand is the lead agency in New Zealand's biosecurity system. It is tasked with a "whole of system" leadership role, encompassing economic, environmental,

social and cultural outcomes. It also has international trade and animal welfare responsibilities.

Biosecurity activities protect the economy, environment and people of New Zealand from the risks and consequences of the introduction of damaging risk organisms, or mitigate the effects of risk organisms that are already present. Biosecurity surveillance plays a vital role in supporting a wide range of these activities.

The targeted marine surveillance programme is administered and funded by MAFBNZ's Biosecurity Surveillance Group. Queries relating to this programme should be directed to MAFBNZ.

The MAFBNZ contact person for all marine biosecurity surveillance activity is Brendan Gould (phone 04 894 0548, fax 04 894 0736, email brendan.gould@maf.govt.nz). Alternatively, the Biosecurity Surveillance Group Manager can be contacted at the following email address: NZBiosecuritySurveillance@maf.govt.nz.

Postal Address:
MAF Biosecurity New Zealand
PO Box 2526
Wellington

NIWA

NIWA has been contracted by MAF Biosecurity New Zealand to design and deliver the surveillance programme to the required specifications.

The NIWA project leaders and contact persons for the targeted surveillance programme are Don Morrissey (NIWA PO Box 893 Nelson, phone 03 548 1715, fax 03 548 1716, email d.morrissey@niwa.co.nz) and Graeme Inglis (NIWA PO Box 8602, Riccarton, Christchurch, phone 03 348 8987, fax 03 348 5548, email g.inglis@niwa.co.nz).

Graeme Inglis and Don Morrissey were also responsible for the design of the programme, with inputs from Isla Fitridge, Oliver Floerl, Nick Gust, Olivia Johnston, Marie Kospartov, Crispin Middleton, Sheryl Miller, John Oldman, Lisa Peacock, Helen Roulston, Matt Smith, Kate Willis and Chris Woods. This team also collated existing data.

Field work was carried out by a large team of NIWA staff (over 40 individuals), with additional support from commercial divers from Northern Underwater Technical Services and Southern Aqua Adventures where necessary. Field teams were led by a core of NIWA staff experienced in targeted surveillance: Niki Davey, Olivia Johnston, Crispin Middleton, Sheryl Miller, Don Morrissey, Kate Neill, Lisa Peacock, Matt Smith and Chris Woods. During fieldwork, field teams were generally divided into two groups, each in a separate boat and each including at least one person with previous experience of surveillance. All field team members are under the authority of the field team leader during field work and in communication by telephone or VHF radio. Field team leaders refer to the project leaders as required.

NIWA's Chief Scientist for Biodiversity and Biosecurity, Don Robertson, can be contacted at d.robertson@niwa.co.nz.

Existing information on the survey location

The following maps (Figures 1a and b) show natural and man-made features and structures in the survey area. Information on sediments in the harbour was obtained from the navigational charts of the area (Land Information New Zealand Charts Numbers 6154, published January 1987, and 6152, published April 1998), and from information on sediment type collected during sled-sampling for previous monitoring surveys (NIWA, unpublished data). Information on shoreline composition (beaches, rocky shores, sea defences, etc.) and artificial structures was obtained from navigational charts, Google™ Earth, the Port Marlborough website, and personal knowledge. Habitat data were mapped by eye, since we are not aware of any sources of georeferenced information. Information from Google™ Earth is georeferenced and coordinates were used to map the structures in GIS.

The water area of the Queen Charlotte Sound at high tide is ca 30,614 ha, the shoreline length is ca 425 km and the spring tidal prism (the volume of water entering on the flood tide) is ca 456 million m³ (information from NIWA's Estuarine Environment Classification database: Hume *et al.* 2007). The ratio of the spring tidal prism to volume at high water is 0.05 (i.e. approximately 5% of the water present in the harbour at high tide leaves on the subsequent ebb). The index of shoreline complexity is 0.14 (this index, calculated from the 1:50,000 topographic map as the reciprocal of the length of the perimeter of the estuary shoreline divided by the circumference of a circle that has the same area as that estuary, varies from 1.0

for a simple circular basin to <0.1 for a very complex shoreline with multiple arms), indicating the complex and indented form of the sound's shoreline.

Figure 1a Map of the sampling area around the Port of Picton and Havelock (upper) and detail of Picton showing habitats and artificial structures present (lower).

Figure 1b Map of the sampling areas around Waikawa Marina (upper) and Havelock (lower) showing habitats and structures present.

EXISTING INFORMATION ON MARINE PESTS

Existing published biological studies that describe marine communities in Picton Harbour are not plentiful (Inglis *et al.* 2006a). However, the baseline survey and resurvey commissioned by MAFBNZ from NIWA in December 2001 (Inglis *et al.* 2006a) and January 2005 (Inglis *et al.* 2006b) have substantially supplemented the available information, although they did not include Havelock. Picton and Havelock were surveyed during the targeted-species surveillance in December 2005. The following summary is taken from Inglis *et al.* (2006b).

Impact assessment studies were conducted for the Shakespeare Bay port development (Duckworth 1987) and the Cawthron Institute has been involved in on-going studies of the flora and fauna of the new port facility in Shakespeare Bay.

A biological inventory of the intertidal communities of Waikawa Bay (in Queen Charlotte Sound five minutes drive northeast of Picton) was produced by Stephenson (1977) for the Marlborough Harbour Board. Of the forty-three species recorded, none were non-indigenous, and only one (the sea anemone *Anthopleura aureoradiata*) was cryptogenic. Species distribution patterns were strongly related to tide and sediment characteristics, but within a given tidal level community structure did not vary greatly between sampling stations. The most abundant animal was the cockle *Austrovenus stutchburyi*, with a maximum recorded density of 2,800 m⁻². The only plant recorded in significant quantity in the study was the eel grass *Zostera muelleri*. Trace metal content in four species of molluscs were analysed and found to be low to moderate.

The invasive kelp *Undaria pinnatifida* was identified in the Marlborough Sounds in 1991, and this area is deemed in the optimal temperature zone for this macroalga (Sinner *et al.* 2000).

Taylor and MacKenzie (2001) investigated the Port of Picton for the presence of the toxic blooming dinoflagellate *Gymnodinium catenatum*, and did not detect resting cysts (sediment samples) or motile cells (phytoplankton samples).

In February 2002, a team of divers surveyed the hull of the steel barge the ‘Steel Mariner’ for “unwanted exotic organisms”. The barge had been moored west of Kaipupu Point in Shakespeare Bay since late 2001 (Coutts 2002). Six algal species and 70 animal taxa were identified on the hull of the vessel. Amongst the species found were two North Island species that do not occur in the south island, the ribbed slipper limpet *Crepidula costata* and the red alga *Cladhymenia lyalli*, and two potential pest species, the “unwanted introduced” *Undaria pinnatifida* and the colonial ascidian *Didemnum vexillum*, known from dense infestations in Whangamata Harbour (Coromandel Peninsula, North Island) and, latterly, Tauranga Harbour (Kott 2002). The surveys estimated that 2,923 ± 628 kg of *D. vexillum* biomass was present on the barge and another 460 ± 180 kg on the seabed. It was considered that offspring of *D. vexillum* from the barge may still have been confined at that time to an estimated 40 m x 80 m area in 5 to 15 m depth below the barge, due to the limited currents in the area and the fast settling time for *D. vexillum* larvae (Coutts 2002).

Because of concern over the potential impacts of *D. vexillum* on long-line mussel aquaculture, an attempt was made, in August 2003, to eradicate the *D. vexillum* infestation in northern Shakespeare Bay (R. Boyce, Port Marlborough New Zealand Ltd., pers. comm.). Dredge material from along the front edge of Waimahara Wharf and from a stock pile on land was used to cover the infested area of approximately 50 m by 30 m, located approximately 750 m northeast from Waimahara Wharf. Approximately 600 m³ of dredge material was used. In October 2003, all the piles of Waimahara Wharf were wrapped and the rip rap under the

wharf was covered in another attempt to smother the *D. vexillum*. The wraps and covers were removed approximately 8 months later as the *D. vexillum* had re-established itself on the surface of the wraps. Some piles have since become re-infested with *D. vexillum* and colonies have subsequently been found on barges and recreational moorings in Shakespeare Bay and on a salmon farm in East Bay (R. Boyce, pers. comm.).

Marlborough District Council produces a State of the Environment Monitoring Report every five years. The 2003/2004 report notes that sediment samples collected from Picton Harbour by Marlborough District Council in March 2004 showed elevated trace metals in harbour sediments, with levels of mercury, copper, lead and zinc exceeding ANZECC guidelines (Marlborough District Council 2004). Tributyltin (TBT) contamination was found at all sites, with a small area of high contamination around Carey's Boatyard, to the east of the Port. Sites closest to the shoreline and boatyard slipways had higher levels of pollution-tolerant polychaete worms and copper concentrations were highest in this area. Shellfish from near the boatyard slipway had slightly higher TBT concentrations. The report notes that the contaminants have been present for a long time and to date have resulted in a low level of adverse effects to benthic animals and shellfish, and will continue to be released from the sediments unless the sediments are removed from the site (Marlborough District Council 2004).

The initial baseline survey of the Port of Picton identified a total of 206 species or higher taxa (Inglis *et al.* 2006a). These consisted of 145 native species, seven non-indigenous species, 27 cryptogenic species (those whose geographic origins are uncertain) and 27 species indeterminata (taxa for which there is insufficient taxonomic or systematic information available to allow identification to species level). Fourteen species of marine organisms collected from the Port of Picton had not previously been described from New Zealand waters. One of these, the ascidian *Cnemidocarpa* sp., was thought to be a non-indigenous species. Another was a cryptogenic amphipod (*Meridiolembos* sp. aff. *acherontis*) and the remaining 12 were species of sponge that did not match existing species descriptions and which may have been new to science.

The seven non-indigenous organisms described from the Port of Picton included representatives of four major taxonomic groups. The non-indigenous species detected were: (Annelida): *Dipolydora armata* and *Polydora hoplura* (Bryozoa): *Bugula flabellata* and *Watersipora subtorquata*, (macroalgae): *Undaria pinnatifida* and *Griffithsia crassiuscula* and (Porifera): *Halisarca dujardini*. The only species on the New Zealand register of unwanted organisms found in the Port of Picton initial baseline survey was the Asian kelp, *U. pinnatifida*. This alga is known to now have a wide distribution in southern and eastern New Zealand. Approximately 57% (four of seven species) of non-indigenous species in the Port of Picton were likely to have been introduced in hull fouling assemblages and 43% (three species) could have been introduced by either ballast water or hull fouling vectors. Ballast water was not attributed as the probable vector for any of the non-indigenous species encountered in the Port of Picton.

A total of 249 species or higher taxa were identified from the re-survey of the Port of Picton in January 2005 (Inglis *et al.* 2006b), consisting of 167 native, 36 cryptogenic, and 11 non-indigenous species, with the remaining 35 taxa being made up of indeterminate species.

The 11 non-indigenous species recorded in the re-survey of the Port of Picton included one annelid worm, five bryozoans, one hydroid, one mollusc, two macroalgae and one sponge (Table 3). Six species found in the re-survey were not recorded during the initial baseline survey of Picton in December 2001. These were: the polychaete *Spirobranchus polytrema*, the

bryozoans *Cryptosula pallasiana*, *Tricellaria inopinata* and *Bugula neritina*, the hydroid *Eudendrium generale* and the mollusc *Theora lubrica*. Only two non-indigenous species recorded in the initial survey (the polychaetes *Polydora hoplura* and *Dipolydora armata*) were not recorded in the re-survey. These two species, both shell-boring worms, are well established in New Zealand and it is likely that these species are still present in the Port of Picton, despite not having been encountered in the repeat survey.

Two of the non-indigenous species (the polychaete worm *Spirobranchus polytrema* and the hydroid *Eudendrium generale*) were recorded for the first time during the initial port baseline surveys; *S. polytrema* was recorded from the ports of Dunedin, Napier and Wellington and *E. generale* was recorded from the Port of Napier. Neither species has previously been recorded from the Port of Picton.

The cryptogenic organisms identified included 11 Category 1 and 25 Category 2 species² (Table 4). These organisms included eight annelids, one bryozoan, one crustacean, two molluscs, 20 sponges and four ascidian species. Only one of the Category 1 cryptogenic species (the nudibranch mollusc *Polycera hedgpathi*) was not recorded in the initial baseline survey of the port, whilst three of the 13 Category 1 cryptogenic species recorded in the initial baseline survey of the Port of Picton was not found during the re-survey (the bryozoan *Rhyncozoon larreyi*, the hydroid *Plumularia setacea* and the amphipod *Aora typica*). Several of the Category 1 cryptogenic species (e.g. the ascidians *Astereocarpa cerea*, *Botrylloides leachii* and *Corella eumyota*) have been present in New Zealand for more than 100 years but have distributions outside New Zealand that suggest non-native origins (Cranfield *et al.* 1998).

Two cryptogenic category 1 species that have recently spread rapidly and which are dominant habitat modifiers are worthy of note. The colonial ascidians *Didemnum vexillum* (Kott 2002) and *D. incanum* were among the cryptogenic Category 1 species recorded in the initial New Zealand port baseline surveys, and one of these species, *D. incanum*, was recorded in the first baseline survey of the Port of Picton. The other species, *D. vexillum*, was first described in 2001 when it formed nuisance growths on ship's hulls, wharf piles and other submerged structures in Whangamata, New Zealand (Kott 2002). It has subsequently been reported from several other port environments including Shakespeare Bay in Picton, Port Nelson and the Bay of Plenty, and a local control programme was trialled in the Marlborough Sounds to prevent its spread to aquaculture sites (Coutts 2002). The detection of *D. vexillum* in New Zealand was followed closely by reports of other nuisance species in this genus from the Atlantic coast of the USA, Mediterranean, North Sea and English Channel, but these now appear to be different species (Kott 2004a). Although the type specimen of *D. vexillum* was described from New Zealand, we have included it in the Cryptogenic 1 category because of uncertainty about its true geographic origins. *Didemnum incanum* is one of the few species of didemnid that occurs both in Australia and New Zealand (Kott 2004b). Unlike *D. vexillum*, there have been no reports of local proliferation by this species (but see below).

The taxonomy of the Didemnidae is complex. The colonies do not display many distinguishing characters at either species or genus level and are comprised of very small, simplified zooids (Kott 2004a). Six species have been described in New Zealand (Kott 2002) and 241 in Australia (Kott 2004a). Most are recent descriptions and, as a result, there are few experts who can distinguish the species reliably. Specimens of *Didemnum* obtained during the

² Category 1 cryptogenic species are those previously recorded from New Zealand whose identity as either native or non-indigenous is unclear. Includes species that may have been introduced to New Zealand before scientific records began and those newly-described species exhibiting invasive behaviour in New Zealand but for which there are no known records outside the New Zealand region. Category 2 cryptogenic species are those newly-discovered species for which there is insufficient information to determine whether New Zealand lies within their native distribution.

initial port baseline surveys were examined by the world authority on this group, Dr Patricia Kott (Queensland Museum). Because, at the time of writing of the report for the second survey, Dr Kott's services had not been secured to examine specimens from the repeat-baseline surveys, these species were reported collectively, as a species group (*Didemnum* sp.)

In the first baseline survey of the Port of Picton, *D. incanum* occurred in pile scrapes taken from Ferry Terminal Berths 2 and 3 and unidentified specimens of Didemnidae (specimens that did not fit the morphological characters for *D. vexillum* or *D. incanum*) were recorded from pile scrape samples taken from Waitohi Wharf and Ferry Terminal Berth No. 2. In the repeat survey of the Port of Picton, species in the *Didemnum* group were recorded in pile scrape samples taken from Waitohi Wharf, Long Arm No. 1 and Shakespeare Bay 2. The divers conducting the pile scrape surveys at Shakespeare Bay 2 also observed that *Didemnum* was carpeting the sea floor at this site.

The targeted-species surveillance of Picton and Havelock in December 2005 recorded *Theora lubrica* in Picton Harbour, Waikawa Marina and Havelock Harbour (it was particularly widespread and abundant at Havelock). *Limaria orientalis* was recorded in Picton, and *Didemnum* sp. was present on Waimahara Wharf in Shakespeare Bay. *Undaria pinnatifida* is abundant and widespread throughout Picton Harbour, including Waikawa Marina, but was not recorded on Waimahara Wharf or in Havelock.

In September 2005, a single individual of *Styela clava* was found on the hull of a launch in Waikawa Marina, following its arrival from the Viaduct Basin, Auckland. The vessel was removed from the water and its hull cleaned. MAFBNZ commissioned NIWA to conduct a reconnaissance survey of the marina to determine whether any other individuals were present. The survey was done on 14 October 2005 and no other individuals were found, nor were any found during the subsequent targeted-species survey of the marina in December 2005.

Table 3 Non-indigenous marine species recorded from the Port of Picton during the first (T1) and second (T2) baseline surveys. Likely vectors of introduction are derived mainly from Cranfield *et al.* (1998), where “H” indicates hull fouling and ‘B’ indicates ballast water transport. Novel non-indigenous species not listed in Cranfield *et al.* (1998) or previously encountered in New Zealand are marked as new records (NR). For these, and other species for which information is scarce, we provide dates of first detection rather than probable dates of introduction.

Phylum, Class	Order	Family	Genus and species	T1*	T2*	Probable means of introduction	Date of introduction or detection (d)	Location in Port of Picton

BIOPHYSICAL CONDITIONS

Data collected off Wedge Point (at the entrance to Picton Harbour) from May 2007 – May 2008 (Figure 2) show that water temperatures around Picton varied between ca 11°C in mid July to ca 21°C in early February. Salinity varied from 32.8 – 35.9 psu over the same period.

Figure 2 Upper: Water temperature (°C) off Wedge Point during 2007-2008. Data were collected at 0.5-m depth. Lower: Salinity (psu) at Wedge Point during the same period. Data courtesy of Mark Gall, NIWA.

HABITAT TYPES WITHIN THE SURVEY AREA

The Port of Picton is located at the head of the sheltered Queen Charlotte Sound, on the north-eastern tip of the South Island of New Zealand (14° 17'S, 174° 00'E). The inner part of the Sound is generally over 20 m in depth. The minimum depth in the main channel west of Long Island is 13.4 m, whilst the alternative channel to the east of Long Island has a minimum water depth of 19.2 m. Neap tidal range is 0.6 m and spring tidal range 1.7 m. The head of Picton Harbour is divided into two bays by Kaipupu Point, with the Port of Picton including facilities in both bays (Figure 1).

Types of habitat present in Picton Port and Havelock, and the surrounding areas, are listed in Table 5. Given that much of the available habitat for incoming non-indigenous species is represented by artificial substrata within the port, calculation of habitat area/volume is not feasible within the present project – there are almost certainly no data on numbers of piles, marina pontoons, etc for the whole port and the available habitat area is structurally extremely complex. As part of the delimitation survey for *Styela clava* (Gust *et al.* (2006), an estimate was made of the length of artificial habitat (piling, pontoons, breakwalls) present in Picton and Havelock ports and marinas. These values, 3,100 m for Picton Port and Waimahara Wharf, 3,600 m for Picton Marina, 4,700 m for Waikawa Marina and 4,800 m for Havelock, were derived from GIS maps of the areas and represent the horizontal length of structures present. Clearly they do not provide an estimate of the area of habitat available for colonisation, but allow a rough comparison among ports. For example, the equivalent value for the largest port in the targeted surveillance programme is 11,300 m for Wellington (including the Burnham Oil Wharf but not including Shelly Bay, or Seaview Wharf and Marina: note that the length of artificial habitat in the Waitemata Harbour and Lyttelton Port were not estimated by Gust *et al.* (2006).

Table 5 Types of habitat present in the survey area.

Habitat category	Habitat type	Habitat subdivision	Location
Soft-surface	Mud		Inner port, marinas, all of Havelock wharf and marina
	Sand		Shallow areas on west side of Picton Harbour between port and marina, and shallow bays outside Waikawa Marina
	Cobble (<20cm)		Shallow areas on west side of Picton Harbour
Hard-surface	Emergent reef		Around shores of Picton Harbour and Shakespeare Bay
	Artificial structures	Commercial vessel berth	Six wharves in Picton Harbour, Waimahara Wharf in Shakespeare Bay, commercial wharves at Havelock entrance (Sanfords wharf) and inner marina (mussel barges, etc.)
		Channel marker	Approaches to Havelock (ca 14)
		Boat ramp	Picton, Waikawa and Havelock Marinas
		Marina (pontoons, piles)	Piles and pontoons at Picton, Waikawa and Havelock Marinas, jetties at inner Picton marina
		Jetty/Breakwater	Jetties in Picton Marina, rip-rap rockwall along moles at Waikawa and Havelock Marinas, concrete breakwalls around Picton Port and Marina and Havelock Marina
		Slipway	One west of Waitohi Wharf and Westshore development ("punt landing"), Picton Harbour, One adjacent to Waimahara Wharf, Shakespeare Bay ("barge berth")
		Moorings	Picton Harbour, Shakespeare Bay
		Bridge (concrete piles)	Road bridge of Kaituna River, east of Havelock (crab condo deployment site)
		Inactive/disused berth	Disused jetties and pontoons berths in outer part of Havelock Marina, due for replacement 2008
		Aquaculture facility	Not in survey area but extensive in other parts of Pelorus and Queen Charlotte Sounds and Tory Channel
Pelagic	Water column	Top, middle, bottom.	

IDENTIFICATION OF VECTOR PARAMETERS

The Port of Picton is currently run by Port Marlborough NZ Ltd (www.portmarlborough.co.nz), established in 1988. It is a relatively small shipping port, but has berths serving both road and rail traffic for the Cook Strait inter-island ferry services. The

port also has wharves for water taxis, commercial launches, vessels at anchor, and large visiting recreational vessels.

The main port activity takes place at Picton, situated at the head of the eastern bay where there are a number of finger wharves including three ferry terminal berths and the Waitohi Wharf (Figure 1). Waitohi Wharf is a general-purpose finger wharf providing berths and facilities for overseas and coastal cargo vessels – mainly those involved in coastal trading (salt loading, cement discharge), fishing and those which sail the Cook Strait. The wharf also serves as the berth for passenger cruise ships, accommodating vessels up to 265 m long.

In 2000, the new deep water port facility, Waimahara Wharf, opened in Shakespeare Bay (Figure 1). This new development complements the port's existing facilities. The 200-m long Waimahara Wharf is designed as a multi purpose berth for timber, logs and coal with the ability to be expanded northwards if required. With a depth alongside of 15.3 m at low tide the wharf provides deep-water access. The addition of mooring dolphins will allow Panamax vessels to be accommodated. Construction of another new berth in an area called the Westshore on the western side of Picton Harbour was completed in the second half of 2005 to provide berth space for commercial fishing vessels.

Berth construction within the port is predominantly concrete deck on a mixture of steel casing (concrete internally) and precast concrete piles with wooden fendering piles.

Within the port, there is no on-going maintenance dredging. Scouring by vessel thrusters and propellers ensures the berths are kept free from sedimentation (R. Boyce, pers comm.).

Between August and November 2005, a 30-m long steel sheet pile berth was constructed on the Westshore of Picton Harbour for commercial fishing vessels, driven through the existing edge of rock batters. This involved some rearranging of the rock wall but no dredging. A slipway was also cut into the northern end of the existing reclamation as part of the construction of boat building premises there. No land reclamation has occurred on the Westshore and no further capital works are currently planned for the Westshore (R. Boyce, pers comm.).

Port Marlborough operates three recreational marinas in the Marlborough Sounds; Picton Marina adjacent to the Port of Picton, Waikawa Marina also within Queen Charlotte Sound, and Havelock Marina at the head of Pelorus Sound. The Picton Marina has 232 floating concrete pier/wooden pile berths for vessels 8-35+ m in length (www.portmarlborough.co.nz). An expansion of the Picton Marina has recently been completed, with a breakwater constructed at Shirley Beach between September and December 2000 and the installation of floating jetties completed around mid 2003. This involved a small volume of dredging along the shore line for berths, with the dredged material placed on land behind sheetpiling (R. Boyce, pers. comm.).

Waikawa Marina has 600 floating concrete pier/wooden pile berths for vessels 8-20 m in length, and 70 additional individual lock-up boat sheds (www.portmarlborough.co.nz). There have been no recent capital works conducted at Waikawa Marina but expansion is currently planned for an additional 500 berths and will include extension of an existing mole and construction of a rubble breakwall (<http://www.marlboroughmarinas.co.nz/Home>).

There are boat ramps at Havelock, Picton and Waikawa Marinas and ramps or slipways for commercial barges at Waitohi Wharf and the western side of Picton Harbour. Approximately 14 channel markers guide ships along the channel into Havelock (not including markers

located on land) and these are administered by Marlborough District Council. The posts supporting the markers are of hardwood or H6-treated timber and the portions of the markers above the low water mark are painted annually and the lights serviced every six months (Dave Marshall, Maritime Officer, Marlborough District Council, pers. comm.). The lights and posts are replaced as necessary (often as a result of random boat damage).

Imports and exports

The volumes and value of goods imported and exported through the Port of Picton are summarised below. These data describe only cargo being loaded for, or unloaded from, overseas ports and do not include domestic cargo (Statistics New Zealand 2006b). Also available from Statistics New Zealand (2006a) was a breakdown of cargo value by country of origin or destination and by commodity for each calendar year; we analysed the data for the period 2002 to 2005 inclusive (i.e. the period between the first and second baseline surveys).

Imports

The Port of Picton received imports from just three countries of initial origin between 2002 and 2005 inclusive (Statistics New Zealand 2006a). Cargo in the “ships, boats and floating structures” commodities class unloaded in 2003 arrived from the Bahamas, whilst the wood and wooden articles unloaded in 2005 came from the Republic of Korea and India.

Exports

The weight of overseas cargo loaded at the Port of Picton increased each financial year between the years ending June 2002 and June 2005 (Statistics New Zealand 2006b). In the year ending June 2005, the Port of Picton loaded 387,295 tonnes of cargo for export, representing a 51.3% increase compared to the 256,004 tonnes loaded in the 2001-2002 financial year. The value of this cargo increased by 14% during this period, with a value of \$33 million in the year ending June 2005. For the financial years ending June 2002 to 2005, overseas cargo loaded at the Port of Picton accounted for 1 to 1.8% by weight and 0.1% by value of the total overseas cargo loaded at New Zealand’s seaports.

The Port of Picton exported cargo in eight different commodity categories between January 2002 and December 2005 inclusive (Statistics New Zealand 2006a). Wood and wooden articles were by far the dominant commodity category by value, representing 96% by value of the cargo loaded and being the only commodity that was loaded for export every year between 2002 and 2005 (Statistics New Zealand 2006a).

The Port of Picton loaded cargo for export to 19 countries of final destination between January 2002 and December 2005 inclusive (Statistics New Zealand 2006a). During this time, the Port of Picton exported most of its overseas cargo by value to the Republic of Korea (74%), and India (17.5%). The Republic of Korea ranked first and India second in all years except 2002, when the People’s Republic of China ranked second.

Shipping movements and ballast discharge patterns

Since June 2005, vessels have been required to comply with the Import Health Standard for Ships’ Ballast Water from All Countries (<http://www.biosecurity.govt.nz/imports/non-organic/standards/ballastwater.htm>). No ballast water is allowed to be discharged without the express permission of a MAF (Ministry of Agriculture and Forestry) inspector. To allow discharge, vessel masters are responsible for providing the inspector with evidence of: discharging ballast water at sea (200 nm from the nearest land, and at least 200 m depth); or demonstrating that ballast water is fresh (2.5 ppt sodium chloride); or having the ballast water treated by a MAF-approved treatment system.

A total volume of 6,956 m³ of ballast water was discharged in the Port of Picton in 1999, with the largest country-of-origin volumes of 1,618 m³ from Japan, 154 m³ from Australia, and 5,184 m³ unspecified (Inglis 2001). This figure is three orders of magnitude lower than the recorded ballast water discharge into the Port of New Plymouth, and two orders of magnitude lower than the volumes discharged in Lyttelton, Tauranga, Whangarei and Nelson Ports (Inglis 2001), providing an indication of the relatively small scale of commercial shipping operations at the Port of Picton.

To gain a more detailed understanding of international and domestic vessel movements to and from the Port of Picton between 2002 and 2005 inclusive, we analysed a database of vessel movements generated and updated by Lloyds Marine Intelligence Unit (LMIU), called 'SeaSearcher.com'. Drawing on real-time information from a network of Lloyd's agents and other sources around the world, the database contains arrival and departure details of all ocean going merchant vessels larger than 99 gross tonnes for all of the ports in the Group 1 and Group 2 surveys. The database does not include movement records for domestic or international ferries plying scheduled routes, small domestic fishing vessels or recreational vessels. Cruise ships, coastal cargo vessels and all other vessels over 99 gross tonnes are included in the database. The database therefore gives a good indication of the movements of international and domestic vessels involved in trade

International vessel movements

Based on an analysis of the 'Seasearcher.com' database, there were 26 vessel arrivals to the Port of Picton from overseas ports between 2002 and 2005 inclusive. These arrived from 6 different countries, with more than half coming from Australia (15 arrivals), and the remainder arriving from China, Korea (both in the northwest Pacific region), Japan, New Caledonia (Pacific Islands), and Aruba (off the South America Atlantic coast). Of the 15 vessels arriving from Australia, four came from ports in New South Wales, four from Tasmania, three from Victoria, two from Queensland and two from South Australia. These were mostly bulk/cement carriers, and this vessel type represented over two-thirds of the total international arrivals.

According to the 'Seasearcher.com' database, during the same period 50 vessels departed from the Port of Picton to 7 different countries. The greatest number of departures for overseas went to ports in the Republic of Korea (northwest Pacific region) as their next port of call (32 movements) followed by the Republic of Singapore (east Asian seas region; eight departures), Australia (five), India (central Indian Ocean region; two departures), and one each for Japan, China (in the northwest Pacific) and the Philippines (east Asian seas). Forty-seven of the 50 movements were bulk/cement carriers, with the remaining three being passenger/vehicle/livestock carriers.

Domestic vessel movements

The 'Seasearcher.com' database contains movement records for 103 vessel arrivals to the Port of Picton from New Zealand ports between 2002 and 2005 inclusive. These vessels arrived from 13 different ports in both the North and South Islands. The greatest number of domestic arrivals during this period came from Wellington (26 arrivals), Lyttelton (20 arrivals), Nelson (15 arrivals), and Napier (10 arrivals). Bulk/cement carriers were by far the dominant vessel type arriving at the Port of Picton from other New Zealand ports (70 arrivals) followed by passenger/vehicle/livestock carriers (20 arrivals).

During the same period, the 'Seasearcher.com' database contained movement records for 77 vessel departures from the Port of Picton to 12 New Zealand ports in both the North and South Islands. The most domestic movements departed the Port of Picton for Wellington (19

movements), Whangarei (13), Napier (11) and Lyttelton (11). Similar to the domestic arrivals, vessels departing the Port of Picton on domestic voyages were mostly bulk / cement carriers (42 movements), followed by passenger/vehicle/livestock carriers (22 movements).

The data described above do not include scheduled ferry movements, or vessels under 99 gross tonnes including fishing and recreational vessels. The Port of Picton facilitates a significant interisland passenger/freight service involving two companies: The Interislander Line and Strait Shipping. Each year Interislander vessels accommodate over one million passengers, 230,000 domestic vehicles and operate over 5,700 sailings (www.interislander.co.nz), while Strait Shipping runs 1,300 return trips between Picton and Wellington annually (www.strait.co.nz). Just seven movement records for these ferries are included in the 'Seasearcher.com' database, signifying the origination or cancellation of a route for a particular vessel. Many fishing vessels are also registered in the Port of Picton (69 in the year 2000, Sinner *et al.* 2000).

Possible vectors for the introduction of non-indigenous species to the port

The non-indigenous species located in the Port of Picton are thought to have arrived in New Zealand via international shipping. They may have reached the Port of Picton directly from overseas or through domestic spread (natural and/or anthropogenic) from other New Zealand ports. Table 2 indicates the possible vectors for the introduction of each non-indigenous species recorded from the Port of Picton during the baseline port surveys. Likely vectors of introduction are largely derived from Cranfield *et al.* (1998) and expert opinion. They suggest that only one of the 11 non-indigenous species (9%) probably arrived via ballast water, 7 species (67%) were most likely to be associated with hull fouling, and three species (27%) could have arrived via either of these mechanisms.

Assessment of the risk of new introductions to the port

Many non-indigenous species introduced to New Zealand ports by shipping do not establish self-sustaining local populations. Those that do, often come from coastlines that have similar marine environments to New Zealand. For example, approximately 80% of the marine non-indigenous species known to be present within New Zealand are native to temperate coastlines of Europe, the northwest Pacific, and southern Australia (Cranfield *et al.* 1998).

The Port of Picton receives comparatively little international commercial shipping compared with other New Zealand ports. Between 2002 and 2005, there were only 26 vessel arrivals from overseas to the Port of Picton recorded in the "SeaSearcher.com" database. The majority of these came from Australia (15) and the northwest Pacific (China and Korea, six arrivals). Most trade vessels arriving in Picton from overseas are, therefore, coming from ports in other temperate regions that have coastal environments similar to New Zealand's. Bulk carriers comprised the greatest proportion of vessel types arriving at Picton from overseas (18 of the 26 arrivals). Empty vessels of these types carry the largest volumes of Cumulative number of taxa ballast water and may, therefore, be more likely to carry invasive species that can be transported in ballast water. In the Port of Picton these vessels came from Australia (nine arrivals), the northwest Pacific (six), Japan (two) and the Pacific Islands (one arrival). Six of the remaining eight vessel arrivals were passenger/vehicle/livestock carriers, which typically discharge relatively small volumes of ballast water. Smaller, slower moving vessels, such as barges, tugs and fishing boats, tend to carry a greater density of fouling organisms than faster cargo vessels. Only two vessels of this type were recorded as arriving in Picton (from Australia) between 2002 and 2005.

Based on shipping patterns at the Port of Picton and similarities in coastal environments, shipping from southern Australia, China, Korea, and Japan present a low, but on-going risk of

introduction of new non-indigenous species to the Port of Picton. Thirteen of the 15 vessel arrivals from Australia recorded in the ‘Seasearcher.com’ data came from southern Australia. Because of the relatively short transit time, shipping originating in southern Australia (particularly Victoria and Tasmania) carries, perhaps, the greatest overall risk. Furthermore, six of the eight marine pests on the New Zealand Register of Unwanted Organisms are already present in southern Australia (*Carcinus maenas*, *Asterias amurensis*, *Undaria pinnatifida*, *Sabella spallanzanii*, *Caulerpa taxifolia*, and *Styela clava*). The native range of other two species – *Eriocheir sinensis* and *Potamocorbula amurensis* – is the northwestern Pacific, including China and Japan.

The small number of international arrivals suggests that the overall risk of introductions directly from overseas ports would be relatively low, and is probably lower than the risk of non-indigenous species being translocated to the Port of Picton from other ports in New Zealand. The Port of Picton is connected directly to the ports of Wellington and Nelson by regular coastal shipping and between 2002 and 2005 received 103 arrivals of commercial shipping vessels from a total of 13 New Zealand ports. The LMIU “SeaSearcher.com” database recorded the majority of vessels arriving in Picton from other New Zealand ports between 2002 and 2005 as arriving mostly from Wellington (26 arrivals), Lyttelton (20 arrivals), Nelson (15 arrivals), Napier (10 arrivals), Tauranga (eight arrivals), Whangarei (eight arrivals) and Timaru (five arrivals), and the majority of these are bulk carriers. These ports (particularly Lyttelton and Timaru) have many non-indigenous species that have not been recorded in Picton, including the unwanted ascidian *Styela clava* (recorded in Lyttelton, the Hauraki Gulf and Tutukaka marina). However, due to its fouling nature, the risk of translocating *Styela clava* is greatest for slow-moving vessels, which comprised only two of the 20 arrivals to Picton from Lyttelton between 2002 and 2005 recorded by the LMIU “SeaSearcher.com” database. Picton is a gateway to the South Island, particularly from Wellington, and other slow-moving vessels such as barges, yachts and pleasure craft arriving from the North Island may, therefore, present an increased risk of introduction of non-indigenous species to Picton. In 2005, *S. clava* was found on the hull of a launch that had recently arrived in Waikawa Marina, Picton, from Viaduct Harbour, Auckland, where *S. clava* is well-established. The launch was removed from the water and cleaned of all fouling. A subsequent search of the surrounding marina did not find any additional specimens (Morrissey 2005). Nevertheless, this incident does highlight the potential for continuing transportation of unwanted species into Picton by slow-moving vessels.

Assessment of translocation risk for introduced species found in the port

Between 2002 and 2005, vessels departing from the Port of Picton travelled to 12 ports throughout New Zealand. Wellington, Whangarei, Napier, Lyttelton, Nelson and Tauranga were the most common next ports of call for domestic vessel movements from Picton (Table 18).

Although all of the non-indigenous species found in the re-survey of the Port of Picton have been recorded in other locations throughout New Zealand, they are not universally present in the other ports. There is, therefore, a risk that species established in the Port of Picton could be spread to other New Zealand locations.

This is illustrated by the one species present in Picton that is on the New Zealand Register of Unwanted Species: the invasive alga *Undaria pinnatifida*. *Undaria pinnatifida* has been present in New Zealand since at least 1987 and has spread through shipping and other vectors to 11 of the 16 ports and marinas surveyed during the baseline surveys (the exceptions being Opua, Whangarei Port and marina, and Gulf Harbour marina). Until recently, it was absent from the Ports of Taranaki (New Plymouth) and Tauranga. Mature sporophytes were

discovered in the Port of Taranaki during the repeat baseline port survey there in March 2005. Sporophytes have also been discovered independently on rocky reefs near the Port of Tauranga, and on wharf piles in the port itself. A small number of vessels travel between Picton and ports north of Auckland where *U. pinnatifida* has not yet become established. There is, therefore, a small risk that it could be spread to these locations by shipping from Picton (or any other location in which it is currently established).

Because it is a fouling organism, the risk of translocating *U. pinnatifida* is highest for slow-moving vessels, such as yachts and barges, and vessels that have long residence times in port. In the Port of Picton, cargo and bulk (including fuel) carriers, recreational craft, and seasonal fishing vessels that are laid up for significant periods of time pose a particular risk for the spread of this species. Such vessels also pose a significant risk of translocation of colonial ascidians in the genus *Didemnum* (classed as cryptogenic category 1 in this report due to uncertainty of their geographic origins). Two species of *Didemnum* that exhibit invasive behaviour have been recorded from the Port of Picton: *D. incanum* (in the initial survey, Inglis *et al.* 2006c) and *D. vexillum* (on a barge moored in Shakespeare Bay, Coutts 2002a). During the re-survey of the Port of Picton, colonies of *Didemnum* were observed carpeting the seafloor near the wharf at Shakespeare Bay. Elsewhere in New Zealand, *Didemnum vexillum* has been reported only from Nelson, Tarkohe, Wellington, Whangamata (Coromandel Peninsula) and the Bay of Plenty, and there is, therefore, a risk that it and other *Didemnum* species could be transported by shipping to other ports where it is not already established. *Didemnum vexillum* has the potential to be a significant fouling pest of aquaculture (particularly longline mussel culture and seafloor scallop enhancement). It may be spread as fouling on poorly maintained commercial or recreational vessels, on fouled ropes and buoys, or other submerged marine structures.

One other non-indigenous species recorded from the repeat survey of Picton, the hydroid *Eudendrium generale*, has a relatively restricted distribution nationwide and could, therefore, be spread from Picton to other locations. Information on the ecology of this species is limited, but it is not known to have potential for significant impacts.

Management of existing non-indigenous species in the port

All except three of the non-indigenous species detected in Picton appear to be well-established in the port. However, the hydroid *Eudendrium generale* and the bryozoans *Tricellaria inopinata* and *Cryptosula pallasiana* were each recorded from only one site in this survey. None of these were recorded from the initial survey of the Port of Picton and thus may not be well established in Picton. However, the bryozoans are present in several other New Zealand ports. In contrast, *E. generale* has only been recorded from two other New Zealand ports (Napier and Wellington).

LOCAL CONSTRAINING FACTORS ON SURVEILLANCE SUCCESS

Local factors likely to constrain sampling, including those representing hazards to field team members, are listed in Table 6, together with management actions to mitigate them.

Table 6 Hazard analysis for biophysical conditions of surveillance locations.

Hazard/Constraining Factor	Effect at Surveillance Location	Present (Y, N or intermittent (I))	Management actions
Water residence time for Queen Charlotte Sound is 15.3 days (Heath 1976) and for Pelorus Sound 9.1 days	Planktonic propagules are likely to remain in the port areas for several days following release, reducing the likely range of dispersal	Y	Trapping and sledding will sample areas outside the immediate port and marina environments to increase likelihood of detecting populations dispersed by water movements.
Turbidity (Secchi disk depth 2.6-4.8 m Picton Harbour, 1.1-2.8 m inner Picton Marina, 2.4-5.0 m Waikawa Marina, 0.5-1.3 m Havelock)	Turbidity high in Picton and Havelock Marinas but low in Picton Port and Waikawa Marina.	Y	Variability in detection probability of diver searches
Most significant wind directions are northerly and southerly because of the shelter provided by surrounding hills), but these can be strong	Boat handling can be difficult in exposed areas during high winds.	I	Picton, Waikawa and Havelock provide sheltered areas to work under most wind conditions, though Picton Harbour and Shakespeare Bay are exposed to northerlies and sampling may have to be adapted to wind conditions.
Tidal currents in the inner parts of Queen Charlotte are not strong because of small tidal range (neap 0.49 m, spring 1.47 m ³). Tidal range in Havelock is larger (neap 1.2 m, spring 2.6 m) but currents are not strong because of limited tidal prism of the area around the port/marina	Little impact on sampling activity	I	
Spring-neap tidal cycle	Spring high tides in Picton occur around midday, with associated suboptimal conditions for shore searches	I	Not a critical factor because tidal currents at Picton and Havelock are not strong and tidal ranges are relatively small
High rainfall can occur throughout the year	High turbidity, risk of sewage spill	I	Sampling (particularly diving) may be postponed after very heavy rain because of poor visibility and (very occasional) sewage contamination
Temperature	Minimum water temperatures in winter are ca 9°C	Y	Diving and other sampling still possible providing divers are adequately equipped (dry suits)
Dangerous animals	Fur seals, eagle rays and sting rays are intermittently present	I	Not generally a problem but should be taken into consideration for dive planning

³ <http://www.linz.govt.nz/hydro/tidal-info/tide-tables/tidal-levels/index.aspx>

Table 6 Continued.

Hazard/Constraining Factor	Effect at Surveillance Location	Present (Y, N or intermittent (I))	Management actions
Vessel traffic	Periodic but predictable for Picton port (Bluebridge and Interislander ferries being the main ones to consider), unpredictable movement of recreational boats in Picton, Waikawa and Havelock and of mussel barges in Havelock (movements mainly at beginning and end of each day)	Y	Sampling of main port can be planned through consultation of Port Marlborough shipping movement website and communication with shipping manager at the start of each survey and during survey work to monitor (common) changes to schedules. Skippers of survey boats need to keep a watch for movements of other vessels.
Dredging & construction activities	No regular maintenance dredging in Picton, Waikawa or Havelock, but occasional capital dredging and construction activity on the port wharves and marina berths	I	May require that parts of the wharves are not sampled at times when construction is in progress, but these periods are usually of limited duration. When dredger is working, sampling vessels need to keep clear and not impede its trips out to the spoil ground.
Cables, pipelines and other hazards to navigation	No cables or pipelines marked on charts of Picton Harbour, Waikawa Bay or Havelock. Wooden debris on mudflats at Havelock that are submerged at high tide.	Y	Boat handlers to keep a look out for any hazardous structures.
Pollution (sewer outfall)	No outfalls within the harbour but sewage spills occur occasionally after heavy rain. Sanford factory outfall on the north mole at Havelock.	I	Diving and other work may have to be postponed until Marlborough District Council posts all-clear notice.
Diving related (entanglement)	Areas that are publicly accessible are heavily used by anglers and fishing line presents an entanglement hazard. Wild oysters are a hazard to exposed skin and diving equipment.	Y	Divers carry knives or shears at all times and boat support with standby diver is always present. Divers also wear gloves to avoid oyster cuts.

PORT SECURITY ISSUES

The port secure area includes Waimahara Wharf, Waitohi Wharf and the Interislander ferry terminal. Other areas are publicly accessible. Because entry to the port area is via the water, rather than by land through the port secure area, field teams are not required to obtain formal security clearance before entering the port (Steve Redshaw, Shipping and Security Coordinator, Port New Zealand Ltd, pers. comm.). Team members are to carry photo-identification when in the port area and will not step onto any area within the port secure area without first obtaining permission from port security. Picton Harbour Radio (monitored by port security) is to be informed as survey vessels enter the port area and prior to divers entering the water at each location within the port.

Selection of sampling methods for target species

HABITAT ASSOCIATIONS AND LIFE HISTORIES OF THE TARGET ORGANISMS

Information on the habitat associations and life histories of the primary target species is collated in Appendix 2.

SELECTING LIFE STAGES TO TARGET

It has been agreed with MAFBNZ that sampling for planktonic lifestages of target organisms is not currently a feasible option and is not included in the scope of the present contract (*Contract Specification Addendum* page 52). Identification of larval stages of target species is generally considerably more difficult than identification of adults. While molecular probes are available for some non-indigenous species, problems of sampling remain unresolved. These include the volume of water to be sampled, the location of samples and the question of how, if the probe gives a positive result, the location (and size) of the source population can be identified. At present, therefore, although these methods may potentially provide presence/absence information on target species, they are of little practical use for managing any incursions detected. A critical part of operationalising molecular probes for field based sampling is testing their specificity for the target organism. That is, although a gene sequence may have been identified for a pest species, we cannot use it reliably in field surveys until its sensitivity to other, related native species has been tested.

SAMPLING METHODS

In comparison to surveys for agricultural pests, survey methods for invasive marine organisms are still relatively undeveloped. Most studies of marine pests have used conventional ecological survey techniques, such as baited traps (Veldhuizen & Stanish 1999, Yamada *et al.* 2001, Thresher *et al.* 2003), diver surveys (Currie *et al.* 2000), and benthic grab (Carlton *et al.* 1990) or sled samples (Parry and Cohen 2001). These methods are relatively non-specific and can be labour-intensive, limiting the number of locations that can be searched effectively. A documented process for the selection of sampling methods and allocation of sampling effort for the target species was developed at the start of the previous phase of the programme (Inglis *et al.* 2006c) and included information on the biology and behaviour of the target organisms and sampling methods used for the same or similar species in other parts of their range. Sensitivity (referred to in previous reports as the “efficiency” of the survey method), cost-effectiveness, feasibility and consistency with safe field-working practice were also evaluated in selecting methods, although in most cases the actual sensitivity of the method has not been quantified.

To decide on appropriate sampling methods for each of the target species, we reviewed published information on methods that had been used previously to sample each species and asked experts working on the species in its native or introduced range to comment on the utility of the methods we had proposed for surveillance monitoring (see Appendix 3). The criteria used to select survey methods were:

- effectiveness at capturing the target species when it is present,
- cost and ease of sampling,
- minimal impact on native marine environments and species, and
- safety of field personnel, the general public and property.

Since the purpose of the surveillance programme is detection, not enumeration, techniques in which the presence or absence of the target species could be determined rapidly within a sample were selected, allowing a comparatively large number of locations to be sampled on each survey. Baited box traps were used to sample adult crabs (i.e. *Carcinus maenas* and

Eriocheir sinensis) and Whayman-Holdsworth starfish traps were used to catch asteroids and other large benthic scavengers. Baited traps do not sample juvenile and subadult *E. sinensis* effectively because these life stages have a largely herbivorous diet. They were therefore sampled with artificial shelters (“crab condos”) designed for surveys of *E. sinensis* in San Francisco Bay. An Ocklemann epibenthic sled was used to sample soft sediment habitats for *Potamocorbula amurensis*, *Sabella spallanzanii*, *Asterias amurensis* and *Caulerpa taxifolia*. Divers searched for *S. spallanzanii*, *C. maenas*, *A. amurensis* and *Styela clava* around piles, floating pontoons and other artificial structures in port and marina environments, and on intertidal and shallow subtidal reefs that were identified as high risk by the dispersal modelling. Timed visual searches for target species were made of intertidal rocky and sandy shorelines.

We considered that the methods selected for the previous phase of this programme (see Table 7) were successful and appropriate, and proposed that they be used in the present study, subject to discussion and approval from MAFBNZ. This was accepted by MAFBNZ, as stated in the *Contract Specification Addendum* (page 51). Note that it has been agreed with MAFBNZ that sampling for planktonic lifestages of target organisms is not currently a feasible option and is not included in the scope of the present contract (*Contract Specification Addendum* page 52).

The minimum size of organism retained by the various trapping and sledding methods is governed by the size of mesh used. In the case of the crab (box) traps the netting covering the trap has a 1.3-cm mesh, that on the starfish traps is 2.6 cm and the bag inside the epibenthic sled has a 2-mm mesh.

Table 7 Summary of proposed sampling methods, target organisms and selection factors.

Method	Target species	Habitat	Spatial coverage	Effectiveness	Cost effectiveness	Feasibility	Previous surveillance in NZ	Previous surveillance overseas
Epibenthic sled tows	<i>Asterias amurensis</i> <i>Caulerpa taxifolia</i> <i>Didemnum</i> sp. <i>Eudistoma elongatum</i> <i>Musculista senhousia</i> <i>Potamocorbula amurensis</i> <i>Sabella spallanzanii</i>	Subtidal soft sediments. Particular focus on known shellfish beds (for <i>Asterias</i>) and areas next to public access (e.g. wharves, boat ramps, marinas, etc. <i>Caulerpa</i> , <i>Sabella</i>)	Narrow width but 50 m tow length and high replication (100+ per location) enables a reasonably large area to be sampled (ca 2500m ² per location)	Reliable sample collection including asteroids, infaunal and epifaunal bivalves and polychaetes and macroalgae	Processing of sled contents can be time consuming	Feasible on all soft-sediment habitats under reasonable weather conditions. Can be limited by the presence of large amounts of benthic macroalgae or soft mud that fill mouth of sled	Yes	Yes
Starfish traps	<i>Asterias amurensis</i> and other motile scavengers	Adjacent to wharf pilings and other artificial habitats	Sampled area is dependent on dispersion of bait odour. High replication possible.	Has been used effectively to monitor <i>A. amurensis</i> in Australia and benthic predators around marine farms in NZ	Quick to deploy and recover, so high replication possible	Most locations and weather conditions	Yes	Yes (Martin & Proctor 2000)
Box (crab) traps	<i>Carcinus maenas</i> <i>Eriocheir sinensis</i> <i>Charybdis japonica</i>	Intertidal and shallow subtidal rocky shores, breakwalls and saltmarsh Particular focus on habitats with complex physical structure (e.g. mussel beds, seagrass beds)	Sampled area is dependent on dispersion of bait odour. High replication possible.	Effectively sample other species of crabs (<i>Ovalipes</i> , <i>Macrophthalmus</i> , <i>Charybdis</i>)	Quick to deploy and recover, so high replication possible	Most locations and weather conditions	Yes	Yes (Hewitt & Martin 2001, May & Brown, 2001 Thresher <i>et al.</i> 2003, Yamada <i>et al.</i> 2004)

Table 7 Continued.

Method	Target species	Habitat	Spatial coverage	Effectiveness	Cost effectiveness	Feasibility	Previous surveillance in NZ	Previous surveillance overseas
Crab condos	<i>Eriocheir sinensis</i> <i>Carcinus maenas</i> <i>Charybdis japonica</i>	Intertidal and shallow subtidal banks of rivers. Particular focus on brackish water habitats with complex physical structure (e.g. saltmarsh or fringing vegetation)	High replication possible. Availability of suitable estuarine habitat may limit deployment	Effectively sample other species of crabs (<i>Helice</i> , <i>Macrophthalmus</i>). Higher rates of detection of crabs than baited traps in muddy river banks (Veldhuizen 2000).	Quick to deploy and recover, so high replication possible	High – access problems at some sites (shallow water, deep mud, private land)	Yes	Yes (Veldhuizen 2000)
Shoreline searches	<i>Eriocheir sinensis</i> <i>Carcinus maenas</i> <i>Caulerpa taxifolia</i> <i>Charybdis japonica</i> <i>Didemnum</i> sp. <i>Eudistoma elongatum</i> <i>Grateloupia turuturu</i> <i>Styela clava</i>	Sloping sandy shorelines, intertidal rocky reefs and areas where drift material is likely to accumulate. Prevailing winds on preceding days are a useful guide to where material may accumulate	Wide – can cover long stretches of intertidal habitat quickly	Used effectively in delimitation studies of <i>Styela</i>	High	High – access to intertidal areas may be limiting	Yes	Yes
Diver searches	<i>Carcinus maenas</i> <i>Asterias amurensis</i> <i>Didemnum</i> sp. <i>Eudistoma elongatum</i> <i>Grateloupia turuturu</i> <i>Sabella spallanzanii</i> <i>Styela clava</i>	Wharf piles, marina piles and pontoons and other artificial structures, intertidal and shallow subtidal reefs.	Good – large numbers of piles or lengths of hard substratum can be searched in detail	Dependent on water clarity and level of biofouling	Cost effective in reasonable water clarity, can be time-consuming under poor conditions	Feasibility dependent on water currents, weather, water clarity and safety issues for divers	Yes	Yes

SURVEILLANCE FOR NON-TARGET SPECIES

The secondary objectives of the programme are:

- To detect incursions of non-target non-indigenous or cryptogenic species not previously recorded in New Zealand
- To detect incursions of established non-indigenous or cryptogenic species that are exhibiting invasive characteristics (i.e. range extensions of established organisms).

This objective will be addressed opportunistically. This is inevitable given the taxonomic range of potential new non-indigenous or cryptogenic species and of established non-indigenous or cryptogenic species that might exhibit invasive characteristics. The diversity of specialist taxonomic skills required to identify this range of taxa is unlikely to be present in any one field team, and collection of all potential material for laboratory identification is beyond the scope of this project. In the previous phase of the targeted surveillance programme we identified a suite of non-target, non-indigenous species known to occur in New Zealand (some of which are now included in the list of additional target species) that were consistently recorded when encountered during surveys (see Inglis *et al.* 2006c and Morrissey *et al.* 2007). In the present phase, we will retain this suite of species, to be recorded along with the primary target species whenever encountered.

These records will be assessed against the criteria of Chapman & Carlton (1991):

- Sudden appearance in the surveillance location⁴
- Has the species spread subsequently
- Association with, or dependency on, non natural dispersal mechanisms
- Strong association with artificial substrate⁵
- Tendency towards monoculture or high local abundance
- Restricted distribution (e.g. only near a likely point of pest introduction by human activities)
- Rapid increase in abundance⁵
- Disjunct global distribution
- Are natural dispersal mechanisms inadequate to reach New Zealand
- Genetic or morphological isolation from most similar species distribution elsewhere in the world.

Note that any one of these triggers may immediately indicate an unknown invasive species, however others, such as abundance or distribution, may only become apparent after further surveillance.

TIMING OF SAMPLING ACTIVITY

In the absence of suitable methods of sampling planktonic life-stages, sampling is done biannually, in summer (November to March) and winter (May to September) at each location to account for possible changes in abundance of adults of the target species. Adults of all of the primary target species are perennial and likely to be present throughout the year. Timing of sampling is constrained by the need to sample all eight locations (ten during the first round of sampling, when Picton and Opuia are also sampled) within each summer and winter period (each survey takes at least a week, with a week in between surveys to allow equipment to be sent on to the next location).

⁴ assumes comparable sampling of artificial and natural substrata has occurred..

⁵ assumes prior knowledge of taxa in surveillance location

DETERMINATION OF SAMPLING EFFORT

MAFBNZ have specified, in consultation with NIWA (as set out in the *Contract Specification Addendum*), that the total sampling effort in each harbour and survey (i.e. total number of sites surveyed and samples taken) will be governed by a fixed cost, since at the time the tender was let, criteria were not specified for the size of infestation to be detected or the desired confidence of detection, both of which are necessary to estimate a statistically robust sample size (Carter 1989, Binns *et al.* 2001). The budget allowed a field team of six people (operating from two vessels) to work in each harbour for up to six days using the six different survey methods. During the first surveillance programme (2002-2004) we established the average time taken to obtain samples with each method and the number of sites that could be surveyed in the allotted time. This varied somewhat among harbours according to the size of the harbour and the availability of suitable habitat for the target species. The initial estimates of sample time were then used to set targets for the numbers of sites sampled with each technique in subsequent surveys. The allocation of effort among the different survey techniques (Table 8) reflected the relative abundance of each type of habitat in the harbours. For example, most sample effort was allocated to sledging (soft-sediment habitats) and crab trapping (structurally complex habitats including wharf structures and subtidal rocky habitats) because these habitats typically covered the largest part of the survey area.

Table 8 Allocation of sampling effort among the survey techniques proposed.

Sampling method	Target number			
	Picton Harbour	Waikawa	Havelock	Total
Crab condo lines ¹	No suitable locations	No suitable locations	8	8
Crab (box) trap lines ²	25	15	20	60
Starfish trap lines ³	9	5	6	20
Epibenthic sled tows	60	20	20	100
Diver searches	15	7	8	30
Shore searches	9	8	8	25

¹ 3 traps per line

² 3 traps per line

³ 2 traps per line

The numbers of samples taken in each harbour during the field surveys in the 2002-2004 sampling programme were similar to those used in the present programme. They generally provided low probabilities of detection of manageable-sized incursions (i.e. <1.5 ha.) for most of the target species (see Inglis *et al.* 2006b for a description of the methods for estimating probabilities of detection). The chance of a sizeable incursion being missed because of statistically low sample numbers, sparse distribution of an incursion and the chance placement of survey locations is amply illustrated by Waitemata Harbour where less than 0.6% of the total linear distance of the artificial structures could be sampled on each survey. As a result, even a relatively large infestation in Waitemata Harbour over a combined linear distance of 1 km could be expected to be found in only one out of every 10 surveys (i.e. probability of detection = 0.11). Such infestations are not usually distributed contiguously, but can be comprised of many small clusters of abundance distributed over a large area. In these circumstances (i.e. statistically low sample number and sparsely distributed incursion) a sizeable incursion can be missed by the chance placement of survey locations.

As stated in the *Contract Specification Addendum*, the elements of the survey design required to set realistic targets for the desired level of confidence and the minimum detectable incursion size may be explored and determined between MAFBNZ and NIWA when available research provides sufficient information on which to base these determinations. The surveillance survey design may then be varied to take account of this new information. It is expected that opportunities for continued improvement will be explored and implemented where appropriate and agreed to during the course of this contract. Determining an appropriate level of sampling requires explicit consideration of the following:

- (1) the minimum size of incursion that is required to be detected by the survey (the “design prevalence”);
- (2) how confident the manager wishes to be that an incursion of that size or greater will be detected (the “confidence of detection”), since absolute confidence is not possible (Cannon 2002; Cameron 2002; Venette *et al.* 2002; Inglis *et al.* 2006c; Hayes *et al.* 2005);
- (3) intuitively, it seems obvious that smaller incursions might be contained more easily than larger ones, but there is little guidance in the literature about how big (or small) such a target should be;
- (4) resources available.

SPATIAL ALLOCATION OF SAMPLING EFFORT

Allocation of sampling effort in the present programme follows the strategy used in previous programmes (Inglis *et al.* 2006c, Morrissey *et al.* 2007). Survey plans were developed for each sampling method and harbour based on the known distribution of habitat for the target species and outputs from the hydrodynamic modelling. We originally anticipated combining the predictive habitat models with the outputs from the plume dispersal simulations in each harbour to identify risk zones in each harbour (the habitat and hydrodynamic modelling are described by Inglis *et al.* (2006c). The area of each habitat in each risk zone (the “search area”) could then be determined and detection limits estimated quantitatively for each zone. However, the major constraint to achieving this was the limited availability of spatially explicit data on the key environmental variables needed to project the predicted habitat distributions in each harbour. Furthermore, because Picton and Havelock were not included in the first phase of the surveillance programme (2002-2004), no hydrodynamic modelling was done for these locations. Consequently, we allocated sampling effort based on our existing knowledge of the distribution of habitats in each harbour, with highest priority given to suitable habitat for the target species and samples allocated in proportion to the relative areas of each habitat.

Because marine organisms are typically aggregated in their spatial distribution, they tend to be absent from, or in comparatively low abundance at most locations and in large densities in relatively few places (Gray 2002). This pattern is even more extreme for the small founder populations of introduced species, which, at least initially, are likely to be absent from most areas and to occur in aggregations at relatively few locations (Gaston 1994). For example, during the initial stages of its invasion of Port Phillip Bay, Australia, the seastar *Asterias amurensis* was found at only two out of more than 70 locations surveyed in the bay (Garnham 1998). This pattern of distribution – locally abundant, but geographically restricted founder populations – suggests that, in most instances, the probability of detection within locations where the species is present is likely to be greater than its expected rarity among locations. Since eradication and control efforts are likely to be most successful when infestations are relatively localised, surveys that optimise the number of locations surveyed will stand the best chance of detecting founding populations with aggregated distributions (Green & Young

1993). Thus, given limited resources, surveying a relatively large number of discrete locations using rapid sampling techniques is likely to be more effective than intensive searches of a few key locations (although there will be a point at which the survey sensitivity is compromised by under-sampling at each location). This basic assumption - the need to sample a large number of survey locations in each harbour - formed the foundation for our choice of survey methods.

Within each harbour, a grid was overlain on the areas to be sampled in GIS (10-m grid-cell size for highest risk areas, such as wharves and marinas, and 50-m grid-cell size in other areas: Figure 3). The individual locations surveyed within each habitat type and stratum were then dispersed uniformly across the grids. Sampling locations were offset by one grid cell for each subsequent survey, so that no location will be sampled more than once over the course of the surveillance programme. These predetermined locations were exported from GIS as map coordinates and loaded into GPS units to allow the field teams to locate positions in the field. Where a preassigned location could not be sampled because of constraints such as the depth of water, presence of a vessel on a berth, or source of danger to the field team (such as areas of high vessel movement), a new location was chosen (referring to maps of past sampling locations to ensure that locations were not inadvertently resampled) and its location recorded and later mapped in GIS.

Figure 3 Example of (upper) the 10x10-m grid used to allocate sampling locations in highest-risk parts of a survey area (Whangarei is used here as an example) and (lower) the 50x50-m grid used in other parts of the survey area. Each dot in the figures represents a grid cell.

SAMPLE LABELLING AND PROCESSING

A documented labelling and audit system for biological samples collected during each survey was developed at the start of the first phase of this programme. It proved to be very effective and provided traceability of samples/specimens from collection to identification. It included the use of standardized recording sheets for each sampling method used and log sheets for material retained for subsequent identification (for both the biological material, material subsampled for DNA analysis, and any photographs taken of the material at the time of

collection). Recording and log sheets were formatted in Microsoft Excel, and data were transcribed to Excel spreadsheets at the end of each survey. Data recorded for each sample included date, time, precise location (including GPS coordinates), method of sampling, numbers of target and selected non-target species collected, individual identifying numbers for any material retained, and environmental data. This system will be retained for the proposed study and will be formally documented in the Design Report for MAFBNZ's approval. Collection and recording of environmental data will include the items listed in Table 10 of the contract. Electronic data recording devices (Hewlett Packard iPAQ hand-held computers) were used during the related port baseline surveys (ZBS2000-04) and their use will be trialled the present study and will be used if they prove reliable and reduce time needed for recording. Copies of the data sheets to be used in the present phase of the programme are included in Appendix 4.

Sample labelling

All samples are sorted on site and any specimen to be retained (all primary target species, representative samples of *Didemnum* sp. and *Eudistoma elongatum*, and any suspicious individuals whose identity is uncertain) is allocated a label (see below) with a unique identifying number (the "sample lot code" including the identity of the port) and placed, with the label, in an individual container for return to the laboratory. The sample lot code is recorded on the sample data sheet against the sample in which it was found, linking the specimen(s) to its exact location and date of collection (which are included on the data sheet – see Appendix 4). Sample lot codes are pre-allocated for each survey so that their format is consistent among surveys and there is no possibility of duplication of codes among or within surveys. The sample lot code, date of collection, method of sampling, sample number, number of specimens retained and a description of the specimens (minimally the relevant taxon) are also recorded on a field sample lot register sheet (Appendix 4.1), providing a list of all specimens retained during the survey in question, by date and type of sample (crab trap, sled, etc.).

Port
and

Sample processing

At the end of each day, all specimens retained are returned to the field laboratory and their labels and sample lot codes checked against the sample register. Where the sample container contains more than one taxon, specimens are separated into taxa and placed in separate containers (suitable for intermediate-term storage – i.e. until they are processed by the Marine Invasives Taxonomic Service - MITS) with a label bearing the sample lot code and a 2-letter taxon code (which will thereafter form part of the unique identifier for that specimen). Specimens are preserved in the chemical appropriate to that taxon (the team member responsible for sample processing is provided with a list of the appropriate fixative and preservative to use with each taxon), and all samples are entered into a sample record sheet (Appendix 4.5), showing the number of individuals of each taxon present in that sample (as identified by the sample lot code).

Taxon-specific methods have been developed for fixing/preserving specimens of target and non-target species (Table 9). Note that specimens will be transferred to the appropriate long-term preserving agent by MITS.

Table 9 Methods for fixing/preserving specimens of target and non-target species collected during surveillance surveys.

Fixing/preserving agent	Taxon	Notes
5% formalin	Algae except bladed red forms	
10% formalin	Ascidians (colonial)	Relax first in menthol and photograph
	Brachiopods	
	Ctenophores	Photograph
	Ectoprocts	
	Fish	Photograph
	Hydroids	
	Jellyfish	Relax first in menthol and photograph
	Nudibranchs	
	Sea anemones	Relax first in menthol and photograph
	Worms	
80% ethanol	Ascidians (solitary)	Photograph
	Bryozoans	
	Crustaceans	
	Echinoderms	Photograph holothurians
	Hard corals	
	Molluscs (no shell)	Relax first in menthol and photograph
	Molluscs (with shell)	
	Soft corals	Relax
	Sponges	Photograph
Other	Red bladed algae	Press. Keep piece for DNA analysis
		(clean off epiphytes, wrap in tissue
		and place in bag with silica gel).

Sample reporting and despatch to MITS

Any suspected Unwanted Species (primary target species, excluding *Styela clava*) or suspected non-indigenous or cryptogenic species not previously recorded in New Zealand will be reported as soon as possible (and within 48 hours) by the field team leader to one of the project leaders (Graeme Inglis or Don Morrissey) who will, in turn, inform the MAFBNZ Exotic Diseases hotline (0800 80 99 66) and the MAFBNZ Biosecurity Surveillance Group Manager (again, within 48 hours of discovery). In the event that the field team leader is unable to contact either of the project leaders within 48 hours, they will contact the hotline and MAFBNZ Group Manager directly. MAFBNZ will issue a submission number to be attached to the specimen (in addition to its existing unique NIWA identifier) and will alert MITS that it is to be dealt with as a priority.

Samples reported via the MAFBNZ hotline will be despatched to MITS as soon as possible. MITS will classify these samples as *urgent* and, where possible, will log them, send them to the relevant taxonomist, and receive an identification back within 48 hours⁶. The person despatching the samples will inform MITS when they have been sent and provide the name of a field-team contact person, and will include a copy of the sample register with the specimens. An electronic version of the sample register will be sent as soon as possible.

⁶ Email correspondence between Brendan Gould (MAFFBNZ) and Shane Ahyong (MITS) 24 July 2008.

All other specimens are then submitted to MITS as soon as possible, and within a week of completion of fieldwork (this allows for travel back to base from remote ports, completion of sample logging, packaging and despatch). If despatch is likely to be delayed beyond a week, MITS and the project leader(s) are to be informed of the delay and advised of the likely date of despatch. This allows for samples to be held until all sampling is completed when this is not possible within the main block of field work, so that all samples from the survey can be despatched together. The person despatching the samples will inform MITS when they have been sent and provide the name of a field-team contact person, and will include a copy of the sample register with the specimens. An electronic version of the sample register will be sent as soon as possible. MITS will treat these samples as *priority* and aim for a 1-week turnaround (from receipt of sample to receipt of identification).

All shipments will need to be accompanied by dangerous-goods documentation appropriate to the preserving chemicals used.

Contact and delivery details for MITS

Delivery details:

Serena Cox
NIWA Marine Invasives Taxonomic Service
NIWA
301 Evans Bay Parade
Greta Point
Wellington
NEW ZEALAND

Contact details:

s.cox@niwa.co.nz

Phone: 04-386-0300 (ext 7364)

Special Requirements:

Please provide MITS with as much advance notice of the dates of fieldwork as possible, to allow preparation.

Data entry and archiving

Data recorded on the field sheets are entered into an Excel spreadsheet (designed in the same format as the datasheets) and checked (not by the same person who entered them).

Coordinates of all sampling locations are then mapped in GIS (ArcView) and all data are imported to a Microsoft Access database for final storage. All files are stored on the project server at NIWA's Greta Point, Wellington campus and are backed up daily. GIS data are currently georeferenced to WGS84 but will be converted to NZGD2000 before being provided to MAFBNZ, along with the Access database.

Acknowledgements

Thanks to John Carter for preparation of maps, Rachel Haskew and John Oldman for hydrodynamic modelling, John Carter and Helen Roulston for development of sample-allocation grids, Shane Ah Yong, Serena Cox, Isla Fitridge and Andrew Hosie for development of the sample-processing protocols, and Isla Fitridge and Liv Johnston for preparation of data sheets. Isla Fitridge, Oli Floerl and Nick Gust are acknowledged for their contributions to the species summaries (Appendix 2). Thanks to Chris Woods for reviewing an earlier version of this report.

Appendices

APPENDIX 1: LETTER SENT TO STAKEHOLDERS.

Fields highlighted in yellow are replaced with appropriate text for each survey at each location.

Targetted surveillance for non-indigenous marine species in New Zealand,

PORT NAME MONTH YEAR

We propose to carry out this survey during the period INSERT DATES. The work will cover the whole of the harbour, including INSERT NAMES OF PORT/WHARF AREAS TO BE SAMPLED.

Background to the survey

The survey is being done by NIWA with funding from Ministry of Agriculture and Forestry Biosecurity New Zealand (MAFBNZ), and repeats the surveillance work done in 2002-2004 at ports around the country. This project provides surveillance for a group of potentially invasive marine animals and plants that MAFBNZ believes present a significant threat to New Zealand. One of them – the sea squirt *Styela clava* – is already present in New Zealand, and in this case the project will monitor its spread). These surveys will be repeated at six-monthly intervals.

Sampling methods

We will be sampling by setting traps for crabs and starfish, dredging for animals on the seabed using a small (1-m wide mouth) scallop dredge, and diving to inspect wharf piles, walls and rocky shores. **All access to port areas will be from the water**, using vessels of 4-6 m length, equipped with VHF radio. We will inform PORT NAME Harbour Radio whenever we enter and leave port areas. INSERT NAME OF ANY MARINAS TO BE SAMPLED will be accessed by boat or from the shore (pontoons). NIWA staff will not board any boat berthed in the marina at any time. ADD INFORMATION RELEVANT TO ANY OTHER STAKEHOLDERS THIS WILL BE SENT TO

- Crab and starfish traps will be deployed on lines with anchors and a marker buoy for periods of 24 hours. Buoys bear NIWA's name and contact telephone number.
- All traps will be deployed away from shipping lanes and will only be deployed on berths when the notice of shipping movements on the INSERT NAME OF PORT AUTHORITY website indicates that the berth will be empty during the period of deployment. We will contact PORT NAME Harbour Radio just prior to deployment to confirm that there have been no changes to advertised shipping movements. Traps in marinas will be placed so that they do not interfere with the movements of vessels. If there is any doubt about deployment we will contact the Marina Manager.
- Dredging and diving around port areas will also avoid shipping lanes, and diving on wharf piles and walls will be timed to avoid shipping movements or the presence of ships on berths. A support boat showing a dive flag will accompany the divers. Again, we will confirm with PORT NAME Harbour Radio prior to

starting to sample. In the marina a surface observer with a dive flag (either in a boat or on the pontoons) will monitor the diver and warn vessels that there is a diver in the water.

We are very grateful to PORT NAME, the marinas and their staff for their cooperation with this project. If you have any questions regarding any aspects of the work, please do not hesitate to contact:

The field-team leader, ADD YOUR NAME, DDI AND EMAIL,

APPENDIX 2: SUMMARIES OF THE HABITAT ASSOCIATIONS AND LIFE HISTORIES OF THE TARGET SPECIES.

Northern Pacific seastar (*Asterias amurensis*)

General information

The northern Pacific seastar, *Asterias amurensis*, naturally inhabits the northern coast of China, the coasts of Korea and Japan, and along the Russian coast to the Bering Strait. It is also found occasionally in Alaska and northern Canada (Morrice, 1995). Its distribution has since increased to several other countries, including Australia.

(<http://www.fish.wa.gov.au/hab/broc/marineinvader/marine01.html>).

Fully-grown seastars reach sizes of 40-50 cm in diameter, with reproduction possible at 10cm, when the seastar is around one year old (CRIMP, 2000). The seastar can increase its diameter by 8cm each year. (<http://www.fish.wa.gov.au/hab/broc/marineinvader/marine01.html>). Increasing size is also a response to food. When food is short the seastars shrink: their sexual organs also shrink which reduces fertilisation success

(<http://www.marine.csiro.au/PressReleasesfolder/99releases/seastar4jun99/backgrnd.html#gaps>).

Timing of reproduction and recruitment

In the southern hemisphere, spawning occurs during winter (July-October) when temperatures are around 10 to 12 °C. Fertilisation takes place externally

(<http://www.parliament.vic.gov.au/enrc/ballast/Ballast-30.htm>). Small eggs of approximately 150µm in diameter hatch, and develop into free-swimming larvae through a series of stages - coeloblast, gastrula, bipinnaria and brachiolaria (Bruce, 1998). A single adult female seastar can produce 10-20 million eggs each year for about 5 years. Both the eggs and larvae are planktonic, drifting in the ocean for up to two months before they settle and metamorphose into juvenile seastars.

(<http://www.parliament.vic.gov.au/enrc/ballast/Ballast-30.htm>). Based on this 60-day larval period, settlement in Australian waters has been shown to occur during mid-September (Parry *et al.* 2001).

The northern Pacific seastar lives for up to five years. It is known to reach outbreak proportions that occur in three to ten year cycles, and which last two to three years

(<http://www.fish.wa.gov.au/hab/broc/marineinvader/marine01.html>).

Habitat and biology

Morrice (1995) suggests that in Tasmanian studies, it is unclear whether the northern Pacific seastar is present in areas due to specific habitat requirements or whether their location is dependant on their rate of spread.

Substratum type

The preferred substrata for *A. amurensis* are mud, sand or pebbles

(<http://www.fish.wa.gov.au/hab/broc/marineinvader/marine01.html>), extending to a mixture of rock, algae and seagrass (Morrice, 1995). It is rarely found on reefs or places subject to high wave action.

However, a benthic habitat is not essential - in Tasmania, both adults and juveniles have been recorded attached to scallop longlines, mussel and oyster lines, salmon cages and spat bags (<http://www.fish.wa.gov.au/hab/broc/marineinvader/marine01.html>). Research has shown that substratum seems important for the induction of settlement and metamorphosis - brachiolaria have shown high rates of settlement on non-geniculate coralline algae, followed by rock and mud. Sand and mussel shell did not induce settlement well. Bacterial cover on mussel lines, accompanied by the fine algae that grows on the ropes, may also provide a very attractive settlement surface (Morris & Johnson, 1998).

Food preferences

The seastar is a predator of many organisms but has a particular preference for shellfish (<http://www.fish.wa.gov.au/hab/broc/marineinvader/marine01.html>). Other prey include sponges, crustaceans, polychaetes and fish (<http://www.parliament.vic.gov.au/enrc/ballast/Ballast-30.htm>), as well as tunicates, bryozoans and echinoderms (Morrice, 1995).

Physiological tolerances (range and preferences)

Temperature

The seastars prefer water temperatures of between 7 and 10 °C in their natural range (<http://www.fish.wa.gov.au/hab/broc/marineinvader/marine01.html>), but can tolerate a range of 5 – 20°C. In Japan, water temperatures above 20°C limit the seastars' range, with adults losing weight and larvae dying above this temperature (Morrice, 1995, Bruce, 1998). The survival of larvae is temperature dependant, with the optimal range being between 8 to 16 °C (Bruce, 1998). However, adult seastars have been shown to adapt to warmer temperatures of up to 22 °C in countries outside their natural range, such as Australia (<http://www.fish.wa.gov.au/hab/broc/marineinvader/marine01.html>).

Depth

The seastar is mainly found in sublittoral to subtidal areas, but can also be present at depths of up to 200m

(<http://www.fish.wa.gov.au/hab/broc/marineinvader/marine01.html>). In Australia, it occurs in the intertidal zone down to a depth of 25m (CRIMP, 2000). Parry & Cohen (2001) have observed that in some parts of Port Philip Bay, the density of the seastar decreases at depths of <15 metres. Morrice (1995) states that in the northern Pacific, the seastar inhabits deeper water in the summer and moves into shallower water in the winter. This may be to survive summer temperatures and to move between areas.

Salinity

Little research appears to have been conducted on salinity tolerances of the northern Pacific seastar, but adults seem to be restricted to salinities above 28 psu (Morrice, 1995). In general, the seastar is sensitive to any changes in salinity and as a result is unlikely to tolerate fluctuating salinities (<http://www.fish.wa.gov.au/hab/broc/marineinvader/marine01.html>).

Optimal salinity for larval survival is 32 psu. The larvae become adversely affected by 10 minute exposures to salinities <17.5 psu and do not survive exposures to salinities <8.55 psu, when extensive cellular damage has been found to occur (Bruce, 1998).

Route of introduction

The most likely route is as seastar larvae contained in the ballast water of international vessels, although research suggests that ‘sea chests’ are another potential method of transport (Dodgshun & Coutts, 2002). Juvenile seastars found on mussel lines in Port Philip Bay, Australia, indicate a further risk of spread (Garnham, 1998).

Methods of sampling

- Parry & Cohen (2001) used a 2.7 m wide peninsula scallop dredge, covered by 25mm mesh to sample *Asterias*. Estimates of field densities were based on the number of seastars collected in a 60 second tow at a speed of 5.7 ± 0.3 knots. The average tow length was around 170 m (Parry & Cohen, 2001).
- Whayman/Holdsworth seastar traps have been designed to catch *Asterias*. Traps with a mesh size of 26mm catch more seastars than larger mesh (65mm) traps. Most seastars are caught within the first 24-48 hours. Pilchards are the more attractive bait but only for short soak times (24-48 hours). The traps effectively fish an area of approximately 30m² (Martin, 1998).
- Vertical distribution of larval asteroids can be measured using vertical tows of a 100µm free-fall plankton net with a 500mm diameter mouth and 5m in length. A choking bridle closes the net when hauled. Vertical tows are undertaken to depths of 5m, the depth at which the net completely submerges, or 15m. A small float can be tied to the end of the plankton net by 10m of fine line – when this submerges, the net has reached the appropriate depth of 15m (Parry *et al*, 2001).

Asian clam (*Potamocorbula amurensis*)

General information

The Asian clam, *Potamocorbula amurensis*, is a native of estuaries from southern China (22° N latitude) to southern Siberia (53° N) and Japan (Cohen & Carlton, 1995). However, it has extended its range to establish abundant populations in California, USA, particularly San Francisco Bay. Asian clams are euryhaline at all stages of development, and reach settlement 17-19 days after fertilisation (Nicolini & Penry, 2000).

Timing of reproduction and recruitment

Field studies in San Francisco Bay suggest that the clam spawns throughout the year, although site-specific seasonal reproduction appears to be related to food supply (Parchaso & Thompson 2002). The eggs are negatively buoyant, so fertilisation and initial development occur in more saline bottom waters. It takes 48 hours for development to the straight hinged larval stage through several life phases – fertilised egg, two-cell stage, four-cell stage, blastula, trochophore). At 17 – 19 days after fertilisation, the bivalve settles at a shell length of approximately 135 µm. Newly settled clams can reproduce within a few months (Nicolini & Penry, 2000). Juvenile clams studied in San Francisco Bay had a mean shell length of 1.7 mm. By the time they were under a year old, shell length was approximately 11 mm (Cohen & Carlton, 1995). Adults generally reach a length of 20 – 30 mm (NZ Ministry of Fisheries, 2001).

Studies in San Francisco Bay have shown that the clam displays a complex picture of patchy recruitment in space and time, which is expected for an invasive eurytopic species (Carlton *et al.* 1990). The zone of greatest recruitment shifts dramatically with changes in flow - high riverine outflow conditions may reduce clam densities, but the clams are quick to repopulate brackish water habitats when high flows abate (Peterson, 1998).

Habitat and biology

Substratum type

The Asian clam is pervasive with regard to habitat. It can invade environments which are nearly freshwater, creeks and sloughs, intertidal sand-mud flats, and on a wide range of subtidal soft bottomed substrata - flocculant mud, coarse sand, peat and hard clay (Carlton *et al.*, 1990). It typically sits with one-third to one-half of its length exposed above the sediment surface. (Cohen & Carlton, 1995). It has been found in very high densities in the benthic layer in the majority of San Francisco Bay estuary, at up to 48,000 individuals.m⁻² (Peterson, 1998). Research in laboratory aquaria has shown that its behaviour can lead to the formation of depressions in the underlying substrate, which can significantly disturb sediment layers to a depth of about 1 cm. The highly altered, complex surface left behind may cause difficulties for other mobile and sedentary infauna, thus allowing the clam to dominate (Carlton *et al.*, 1990).

Feeding

Potamocorbula amurensis is an efficient suspension feeder (Thompson *et al*, 1991). Examination of faeces from specimens collected in San Francisco Bay show that the clam ingests both planktonic and benthic diatoms. It also filters bacterioplankton as well as phytoplankton, though at lower efficiency, and assimilates both with high efficiency. Laboratory experiments have shown that the bivalve can also readily consume certain copepod nauplii (Kimmerer *et al* 1994). Other research suggests it may feed on the larvae of other benthic organisms (Cohen & Carlton, 1995).

Physiological tolerances (range and preferences)

The Asian clam is one of the few species of bivalves able to tolerate virtually any salinity, withstand tropical or cold temperate waters and survive in polluted environments. Research in San Francisco Bay suggests that the Asian clam has spread rapidly, irrespective of sediment type, water depth and salinity (Thompson *et al*. 1991). The following information highlights the wide range of physiological tolerances that this species displays.

Temperature

Their latitudinal range in Asia suggests that Asian clams can survive a temperature range of 0 – 28°C (Cohen & Carlton, 1995). There is very little information for *P. amurensis*, but data for the similar Chinese corbulid *P. laevis* (found at approximately the same latitude as San Francisco Bay) suggest that gametogenesis requires water temperatures ranging from 12 – 23°C. Reproductively active *P. amurensis* have been seen in San Francisco Bay in water temperatures ranging from 6 – 23°C (Parchaso and Thompson 2002). Fertilised eggs of *P. laevis* are shed at temperatures of between 16 and 20°C. Growth rates are greatest when water temperatures are between 22 and 28°C. Growth rates decline below 17°C, and growth ceases below 11.8°C (Carlton *et al*, 1990).

Depth

The clams live both subtidally and intertidally (Cohen & Carlton, 1995), but primarily subtidally (Carlton *et al*, 1990).

Salinity

The Asian clam can survive in a range of salinities from almost freshwater (< 1 psu) to full-strength seawater (32 – 33psu) (Cohen & Carlton, 1995, Carlton *et al*, 1990, <http://www.fish.wa.gov.au/hab/broc/marineinvader/marine08.html>) but long-term survival of adults is highest at salinities from 5 to 25 psu (Nicolini & Penry, 2000). Spawning and fertilisation can occur at salinities from 5 – 25 psu, with a maximum at about 10 – 15 psu. Eggs and sperm can tolerate at least a 10-psu step increase or decrease in salinity. Studies have shown that fertilisation and initial development tend to occur in the more saline bottom waters of San Francisco Bay. Embryos of two hours old have been shown to tolerate salinities from 10 – 30 psu, and at 24 hours old they can tolerate the same wide range of salinities that adult clams can. However, any *rapid* changes in salinity may adversely affect larval growth (Nicolini & Penry, 2000).

Route of introduction

The initial introduction of the Asian clam to San Francisco Bay seems to have been as veliger larvae transported in ballast water by trans-Pacific cargo ships. The clams' ability to tolerate wide changes in salinity suggests it can survive incomplete oceanic exchanges of ballast water (Nicolini & Penry, 2000). The infaunal habitat of the clam suggests that it did not arrive as a fouling organism (Carlton *et al.*, 1990).

Methods of sampling

- Carlton *et al.* (1990) described a combination of sampling devices that were used to sample *Potamocorbula*, including a modified Van Veen grab, a Ponar grab and a Van Veen grab, that sampled between 0.05 and 0.1 m² of sediment. Samples were sieved through screens of 0.5 mm to 1mm mesh size. Between 3 to 5 replicate grabs were taken at each sampling station.
- Peterson (1998) describes an extensive survey for *Potamocorbula* in San Francisco Bay using a Ponar grab.

Chinese mitten crab (*Eriocheir sinensis*)

General Information:

The Chinese mitten crab *Eriocheir sinensis* is a burrowing crab native to mainland China and coastal rivers and estuaries of the Yellow Sea. It is a palm-sized greyish-brown grapsid crab with small white pincers protruding from hairy brown claws. The native range of the mitten crab extends from the southern border of North Korea (40°N latitude) to Hong Kong (22°N). It has established introduced populations in Vietnam, northern Europe and the west coast of America. The first specimens to be found in Europe were reported from near Hamburg in Germany 1912 (Panning 1939). Since then, mitten crabs have spread from Finland to the Atlantic coast of southern France and to the UK, Russia, Holland, Belgium, the Czech republic, Denmark, Sweden, France, Poland and Portugal and Spain. The first reported occurrence of the mitten crab in North America was in the Detroit River in 1965 by the city of Windsor, Canada. Later, in 1973, commercial fishermen netted several crabs in Lake Erie near Erieau and Port Stanley, Ontario, Canada (Nepszy & Leach, 1973). In June 2006 a specimen was caught in Chesapeake Bay (SERC 2004). On the west coast, it was first reported from San Francisco Bay in 1992 where it has since become well-established (Halat & Resh 1996). Ballast water introductions have been blamed, but speculation also exists about possible deliberate release into the U.S.A.

Eriocheir sinensis is a catadromous species that lives most of its life in freshwater environments. Mature males and females migrate during late summer to tidal estuaries where they mate and spawn. Adults (Maximum body size 10-cm carapace width, but more commonly between 5 and 8 cm) are capable of very long distance migrations e.g. over 1000km in the Yangtze River (Cohen & Carlton 1995). After mating the females are thought to continue seaward, over-wintering in the deeper water and returning to brackish water in the spring to hatch their eggs (Panning 1939). The movement of crabs to deeper water and the timing of egg hatching/larval release is temperature dependent. Winter temperatures are much colder in Europe than San Francisco, which is probably why crabs there move to deeper water and why hatching is delayed until spring. In the San Francisco Estuary, preliminary data indicate that the adult crabs remain in the spawning areas (~ 20psu) and hatching occurs in November/December and again in March. The timing of hatching varies yearly depending upon winter water temperatures. Settled juvenile crabs gradually move upstream into brackish (1-5 psu) and fresh water to complete the life cycle.

Mitten crab 'plagues' of extreme numbers have been reported from Germany in the mid 1930's (Panning 1939) and in the Netherlands in 1981 (Ingle, 1986). Adults are capable of emerging from water and crossing dry land when migrating.

Timing of reproduction and recruitment

Crabs mature at different ages according to locality. Maturity has been reported at ages of 3 to 5 years in Europe (Panning 1939), 1 to 2 years in China (Cohen & Carlton 1995) and 2 to 3 years in California (Veldhuizen and Stanish 1999). Each female produces from 250,000 to 1 million eggs, which hatch in late spring or early summer. In laboratory culture, the larval period lasts for 1–2 months and the larvae develop through five zoeae and a megalopa stage (Kim & Hwang 1995). After the final larval moult the juvenile crab settles to the bottom in late spring and begins its migration upstream (Panning, 1939; Ingle, 1986; Anger, 1991). Experiments indicate that complete development of larvae is not possible in rivers or in brackish estuarine conditions (Anger 1991).

Habitat and Biology:

Substratum type

The normal habitat of the juveniles is the bottoms and banks of brackish and freshwater rivers and estuaries, individuals prefer hard bottoms and areas covered with submerged plants (Nepzy & Leach 1973). Older juveniles are found in a diversity of habitats including silt, gravel, and open unvegetated stream channels. In freshwater habitats of San Francisco Bay, *E. sinensis* is most common in areas with steep, vegetated banks that are high in clay content. Burrows are concentrated underneath the root profile of the aquatic macrophytes lining the banks, which mainly consists of *Scirpus* (Halat & Resh 1996). Submerged aquatic vegetation is an important component to the habitat. It provides cover and high concentrations of invertebrates (Veldhuizen 2000).

In Asia and Europe mitten crabs live in burrows dug in river banks or in rice paddies in coastal areas (Cohen & Carlton 1995). Young mitten crabs are found in tidal freshwater areas and usually burrow in banks and levees between high and low-tide marks. Optimal rearing habitat for juveniles is areas with still or slow velocity water, a stable water depth, low turbidity, and warm temperatures (ranging from 20°C to 30°C, with optimal growth at 24°C to 28°C) (Veldhuizen 2000). Mitten crabs apparently do not burrow as extensively in non-tidal areas. Older juveniles are found further upstream than young ones and both adults and juveniles can move hundreds of km.

In China, recently settled juvenile mitten crabs are harvested during spring tides in late May and June when they congregate over sandy bottom areas in water of 1 to 3 ‰ (Hymanson *et al.* 1999)

Food preferences

The mitten crab is known to be predominantly an omnivorous, opportunistic feeder, although feeding habits change as they mature. Juvenile crabs mainly eat vegetation (Halat & Resh 1996) primarily filamentous algae (Veldhuizen & Stanish 1999). As they mature they also prey on small invertebrates, especially worms and clams so that adults and juveniles are considered omnivorous (<http://www.wsg.washington.edu>). Gut content analysis of crabs in the San Francisco Bay area revealed a high proportion of vegetative matter, with low amounts of invertebrates, regardless of the size of the crab or the habitat from which it was captured (Rudnick *et al.* 2000).

Vegetation type

Juveniles were observed taking cover in floating vegetation, especially water hyacinth in the USA (Hieb & Veldhuizen 1998). An ongoing study by Veldhuizen is currently assessing habitat

associations for this crab in the San Joaquin Delta, but results are presently unavailable. In Asia, the juveniles can be associated with rice paddies (Panning 1939). An attempt to characterise habitat associations of mitten crabs in the San Joaquin River in 2000 failed to capture any individuals (May & Brown 2000).

Physiological Tolerances (range and preferences):

Temperature

Adult mitten crabs exhibit a wide range of temperature tolerances. Growth ceases only at temperatures below 7°C and above 30°C (Rudnick *et al.* 2000). All larval stages of the Chinese mitten crab show a clear preference for warm water, however (15° to 18°C), and temperatures below 12°C do not allow any development beyond the first zoeal stage in the laboratory (Anger 1991). Adults can tolerate temperatures as low as 0 °C for a week and temperatures up to 31 °C are suitable for juveniles (Veldhuizen & Stanish 1999).

Depth

Juvenile mitten crabs appear to occur mostly in shallower waters (i.e. < 10m) (Veldhuizen & Stanish 1999, preliminary results), with largest densities found in areas with an average depth of 2 m, which corresponds to the depth of submerged aquatic vegetation (Veldhuizen 1999). However, through the winter sexually mature females are thought to move to “deep” water to develop their fertilised eggs. Adult mitten crabs are highly tolerant of desiccation and are able to remain on land for several hours without mortality. Veldhuizen (pers. comm.) compared the relative abundance of juvenile mitten crabs among six different habitat types - shallow (0-2.4 m) vegetated natural substrate, shallow unvegetated natural substrate, shallow vegetated rock substrate, shallow non-vegetated rock, mid-depth channels (2.5 – 4.9 m), and deep channels (5 - 10 m) - that occurred in a tidal freshwater marsh. Crabs occurred in all habitat types, but were overall more abundant in shallow (0 to 2.4 m) vegetated areas with natural substrate. Most of the crabs ranged in size from 20 to 38 mm, average size was 28 mm.

Salinity

Juvenile and adult Chinese mitten crabs are extremely euryhaline (i.e. high range of tolerated salinities) and its osmoregulatory abilities appear well developed (Onken 1996). By hyper-regulating the ionic content of their body fluids, the crabs can quickly adapt from high to low salinity environments (Welcomme & Devos 1991 cited in Rudnick *et al.* 2000). Different larval stages are known to vary in their salinity tolerances. The first zoeal stage, which occurs in seawater, is strongly euryhaline, but successive zoeal stages become increasingly stenohaline (low range of tolerated salinities) and prefer more typical marine salinities (e.g. >30 psu). The megalopa, which migrates to freshwater, is euryhaline, with an optimal growth response in brackish waters (5-25 psu) (Anger 1991). Salinities in the areas where *E. sinensis* has been found range from 0-5 psu in San Francisco Bay (Halat & Resh 1996). It cannot spawn in fresh water and larval growth cannot go to completion in rivers or brackish waters (Anger 1991). Mating and fertilisation in the San Francisco estuary occur in late autumn and winter, generally at salinities of 15- 20 psu. In China, most mating occurs in brackish water (10 – 16 psu) (Hymanson *et al.* 1999). A large increase in the abundance of this species in England coincided with a drought and a large change in the salinity of the estuaries they occupied (Atrill & Thomas 1996).

Methods of Sampling:

Methods of sampling mitten crabs need to differ between adults and juveniles to reflect their different diets and habitats. Adults migrate downstream in late summer to spawn. These crabs are sexually mature. Only juveniles migrate upstream. Juveniles are found in creeks, rivers, and tidal freshwater and brackish marshes and sloughs. Juveniles burrow and occupy burrows but also remain in the subtidal zone.

- Panning (1938) found that because juveniles are mostly vegetarian, capturing them with baited traps didn't work and they had to be excavated from their burrows during low tides. Capturing juveniles in the USA has involved intertidal searches at low tide where all cavities such as burrows and root tunnels were excavated and all debris, driftwood and small puddles were examined. Juveniles were also successfully captured in 'crab condos', submerged artificial structures of PVC tube used for shelter.
- A comparison of trapping techniques by Veldhuizen *et al* (1999) suggested that traditional crab sampling techniques are not very effective for this species due to the change in diet between juveniles and adults, the diversity of habitats occupied, and their escape tendencies. For juvenile crabs she recommends using artificial shelter substrates ("crab condos") made of 12 vertical PVC tubes (6 in long, 2 in diameter) and burrow searches for juveniles in the banks of silty, tidally influenced streams. Crab condos are typically submerged for 48 hours to allow the crabs to enter (Veldhuizen 2000), but significant increases in catch are achieved with longer soak times (3, 5 and 9 days).
- Beach seining for adults was possible in shallow intertidal areas and subtidal areas. Baited traps were not recommended for juvenile mitten crab, or for monitoring and detection programs where adult densities may be very low.
- Various other baited traps, snares and ring nets have also been trailed, with variable success. Ring nets are most successful when densities of crabs are high. The crabs appear to be most active in the two weeks surrounding the full moon.

Impacts

The crab has caused numerous problems in Europe when found in extremely high densities. The burrows that it excavates can destabilise river banks and lead to accelerated bank erosion. The sharp claws of *E. sinensis* cut up commercial fish nets, increasing operating costs of fishing operations. The most widely reported economic impact of mitten crabs in Europe has been damage to commercial fishing nets and the catch when the crabs are caught in high numbers. Because of the severe problems the crab has caused in European waters, *E. sinensis* recently has been listed as a federally injurious species in the United States.

The ban on importing live Chinese mitten crabs to the USA was enacted due to concern over potential damage from its burrows to levees or rice fields in the Central Valley, and because the crab is a second intermediate host of a human parasite, the oriental lung fluke *Paragonimus westermanii* (Cohen &

Carlton 1995). The Chinese mitten crab has been widely reported to be an intermediate host for the Oriental lung fluke, a parasite that uses a snail as its primary host, freshwater crayfish and crabs as intermediate hosts, and a variety of mammals, including humans, as final hosts in its life cycle (Chandler & Read 1961; Lapage 1963). Humans can become infected with the parasite through ingestion. The fluke settles in the lungs and other parts of the body, and can cause significant bronchial or, in cases where it migrates into the brain and/or muscles, neurological illnesses. It is believed that no species of snail that is in the family of the primary host currently occurs in Europe, and no appropriate snail host has been found in the San Francisco Bay-Delta system (Clark *et al.* 1988; Veldhuizen & Stanish 1999). Armand Kuris and Mark Torchin of U. C. Santa Barbara found no parasites of any kind in 25 mitten crabs from San Francisco Bay (A. Kuris, pers. comm., 1995).

The potential ecosystem impacts of large numbers of crabs invading new areas are unknown but authors have often speculated on possible effects to benthic invertebrate communities. There is concern that the crab will consume benthic invertebrates, salmon and trout eggs and may affect other species through direct predation or competition for food resources. In England there is some concern that it may compete with the native crayfish in fresh water (Clarke *et al* 1998). In China and Korea Juvenile mitten crabs have been reported to damage rice crops by consuming the young rice shoots and burrowing in the rice field levees. Since *E. sinensis* often inhabit areas that may contain high levels of contaminants, bioaccumulation of contaminants could also be transferred to predators or humans.

European green crab (*Carcinus maenas*)

General information

The European green crab, *Carcinus maenas*, is native to the Atlantic, Baltic and North Sea coasts of Europe, but has established populations outside this range on the Atlantic and Pacific coasts of North America, in South Africa, and Australia. Green crabs produce planktonic larvae that pass through six developmental stages – a prezoea, 4 zoeal stages, and a megalopa – before metamorphosis to the benthic, juvenile crab phase. The crabs themselves grow through 18 to 20 moult cycles before reaching maximum size and terminal anecysis (Parry *et al.* 1996). In its native range, the green crab can live up to 5 years and males reach a size of 86 mm carapace width. In western North America, adult males can be up to 92 mm carapace width within 2 years (Grosholz & Ruiz 1996).

Timing of reproduction and recruitment

Green crabs mate after the females moult, usually between spring and autumn. In warmer waters, females carry eggs for around four months. Egg-bearing females tend to migrate into deeper water during winter and prezoeae hatch from the eggs predominantly in spring (<http://www.wa.gov/wdfw/fish/ans/greencrab.htm>). The prezoeae pass through four zoeal stages in the plankton before moulting into the megalopal stage. Megalopae appear in early-mid summer and metamorphose and settle into the juvenile crab phase in late summer (Parry *et al.* 1996). The average development time for *C. maenas* larvae varies with temperature. At 10°C development takes around 75 days, and at 25°C it can take as little as 13 days (Parry *et al.* 1996). The timing of settlement is related to the number of months in which water temperatures are below 10°C. In cooler waters, settlement occurs in late summer. In warmer waters, megalopae can begin to settle in late autumn (Yamada *et al.* 2001). Settlement occurs predominantly at night around the time of high tide (Zeng *et al.* 1997).

Habitat and biology

Substratum type

In its native range, the Green Crab, *Carcinus maenas*, occurs on both hard (rocky) and soft intertidal and shallow subtidal habitats in semi-exposed soft-sediment bays (Moksnes 2002). In Europe, eastern North America, Australia and South Africa, green crabs occur in protected embayments and on moderately exposed rocky shores. In western North America green crabs occur only in sheltered embayments and only in soft-sediment environments (Grosholz & Ruiz 1996). A recent survey of the distribution of *C. maenas* in southern Australia found crabs in a range of soft-sediment habitats in low energy embayments. Substratum type, depth and water quality were all poor predictors of its presence and abundance in traps set in these habitats (Thresher *et al.* 2003).

Post larvae (megalopae) settle and metamorphose predominantly in shallow (< 1 m) sheltered or semi-exposed areas that have some form of structured habitat that provides shelter from predators (e.g. seagrass, macroalgae, mussels, shell debris, etc). Small crabs are often found in close proximity to vegetation such as beach grass, reeds, and eelgrass, although they also occur in exposed areas such as bare mud. Larger crabs do not need vegetative cover. In Sweden, young crabs are concentrated in greatest densities within structurally complex habitats, such as mussel beds, shell debris, seagrasses

and filamentous algae. Much smaller densities occur in adjacent sand or mud. Densities of juvenile crabs (2nd – 9th instar) are significantly greater in mussel beds and shell habitats (mean = 206 crabs.m⁻²) than in eelgrass (45 crabs.m⁻²), filamentous green algae (24 crabs.m⁻²) or sand (13 crabs.m⁻²). Settlement of megalopae occurs predominantly to structurally complex habitats such as filamentous algae (231 settlers.m⁻²), eelgrass (159 settlers.m⁻²) and mussel beds (114 settlers.m⁻²), rather than to open sand (4 settlers.m⁻²), but larger animals redistribute themselves among these habitats. Indeed, adult crabs are highly mobile and are capable of foraging over large areas (km to 10's km).

Food preferences

Green crabs are omnivorous. Adult crabs feed predominantly on bivalves (rank = 1), small crustaceans (rank = 2) and smaller numbers of polychaetes and green algae (rank = 3 to 4) (Grosholz & Ruiz 1996).

Physiological tolerances (range & preferences)

Temperature

Carcinus maenas can tolerate a wide range of temperatures. In its native and introduced ranges, animals can tolerate average summer water temperatures of 22°C and average winter temperatures of 0 °C, although adult mortality has been recorded at sustained winter temperatures of 0 °C or below (Cohen *et al.* 1995). Crabs stop moulting and drastically reduce their activity below 10°C, and stop feeding when temperatures are below 7°C (Yamada *et al.* 2001). Successful embryonic development occurs at temperatures between 11 and 25 °C.

Depth

Green crabs are found predominantly in the mid-intertidal zone, between about 1.3 m to 1.7 m above datum, and shallow subtidal, although adults have been recorded as deep as 60 m (Cohen *et al.* 1995). Juveniles (0-1+ age, 1-20 mm carapace width) are found mainly < 1 m water depth (Moksnes 2002). In Bodega Harbour, California, green crabs were caught between +0.7m and 1.4 m above mean lower low-water, with crabs being most abundant at +1.2 m (Grosholz & Ruiz 1995: see Figure 3). Parry *et al.* (1996) and Thresher *et al.* (2003) report greatest catches of adult *C. maenas* in water depths < 10 m. However, in Sweden, subadults and adults are found commonly between 0.1 to 20 m depth (occasionally to 60 m).

Salinity

Green crabs tolerate a wide range of salinity, but appear to prefer more saline areas (Proctor 1997). Adults reside in water from 4 psu to 34 psu. Populations breed successfully at salinities down to at least 13 psu, although larvae may only settle at salinities above 17 psu (Cohen *et al.* 1995). Survival of eggs to larval stages occurs at salinities between 26 and 39 psu and larval development may be prevented at < 13 psu (<http://www.wa.gov/wdfw/fish/ans/greencrab.htm>). In the laboratory, adult *Carcinus* prefer salinities of 22-41 psu, but can tolerate maximum salinities of up to 54 psu (Cohen *et al.* 1995).

Methods of sampling

- Standard baited minnow traps (cylindrical with inverted cone entrances of ~ 57 mm) are set near the edge of vegetation or along mud/peat banks, generally far from the low tide drainage channels. Set 5-10 traps with openings perpendicular to the incoming tide with a rock in the trap to hold it in place, and possibly a rock "cradle" made in the substrate to keep the traps from being moved by wave action (http://www.pac.dfo-mpo.gc.ca/ops/fm/shellfish/Green_Crab/FIND.HTML).
- Shore searches along the high tide wrack line where storm driven vegetation accumulates for exuviae of molting crabs. This is most profitable in areas with some vegetation intertidally or subtidally, as molting crabs prefer to have cover available during this vulnerable process (http://www.pac.dfo-mpo.gc.ca/ops/fm/shellfish/Green_Crab/FIND.HTML).
- Yamada *et al.* (2001) compared 4 types of traps for catching *Carcinus*: unbaited pitfall traps, minnow traps, fish traps and box traps deployed in intertidal and shallow subtidal environments. In high intertidal areas, pitfall traps were successful for sampling crabs < 45 mm carapace width. Folding traps and box traps successfully caught crabs > 40 mm. The box traps typically yielded larger catches than other types and caught crabs in their second or third summer.
- Thresher *et al.* (2003) used collapsible box traps (62 cm x 42 cm x 20 cm) to survey populations of *C. maenas* in southern Australia. Traps were typically baited with oily fish and deployed over night for 15-24 hours. Average catch rates from a single overnight set were occasionally as high as 44 crabs.trap⁻¹.

Mediterranean fanworm (*Sabella spallanzanii*)

General information

Sabella spallanzanii is a large (up to 70 cm length) tube-building polychaete that is native to the Mediterranean and Atlantic coasts of Europe. Introduced populations of *S. spallanzanii* have been recorded in Brazil, and in the southern states of Australia (Western Australia, South Australia and Victoria) where it occurs in large densities attached to a variety of substrata. The worm's tubes are constructed of a tough but flexible material with the outer layer often incorporating deposits of silt and mud. The base of the tube is usually secured to hard substrata such as rocks, jetty pilings or shell fragments (Clapin & Evans 1995), but they may inhabit soft sediments where there are some solid particles (e.g. shell fragments, pebbles) on which the tubes can attach.

Timing of reproduction and recruitment

Sabella spallanzanii is a gonochoric broadcast spawner that releases strings of mucus containing eggs or sperm into the water column (Giangrande *et al.* 2000). Worms attain sexual maturity at around 50 mm length after 6 months of growth. Spawning is thought to occur in autumn and winter in Victoria (Currie *et al.* 2000), although there is some evidence for summer spawning in Western Australia (Clapin & Evans 1995). Females are highly fecund and can produce >50 000 eggs which appear to be fertilised either internally or in situ (Giangrande *et al.* 2000). The fertilised egg masses are negatively buoyant and sink rapidly to the bottom (Giangrande *et al.* 2000). As the egg membrane disappears, free-swimming trochophore larvae emerge. These larval stages have a planktonic life of up to 21 days before they settle to the adult habitat. Settling larvae are gregarious and new recruits often occur in dense clusters. In Victoria, small worms (10-14 cm length) have been recorded in late November (Parry *et al.* 1996). Larvae spend about 2 weeks in the plankton before they settle and metamorphose (CRIMP 2001), but appear to travel only short distances (<20 km) from their parent stock prior to settlement (Parry *et al.* 1996).

Habitat and biology

Substratum type

Sabella spallanzanii grows preferentially in sheltered, nutrient enriched waters that are not subject to waves (Currie *et al.* 2000). In its native range it occurs predominantly on hard substrata and, in Port Phillip Bay, Australia, it is particularly abundant on man-made hard surfaces such as wharf pilings, channel markers, marina piles, etc. It is not common on the hulls of ships (Giangrande *et al.* 2000). Largest densities occur on hard surfaces between 2 m and 7 m depth (Currie *et al.* 2000). In unconsolidated sediments, *Sabella* occurs in areas where suitable attachment substrata (rocks, concrete, wood, steel, bivalves, ascidians, etc) are present and tends to be aggregated in smaller densities. Although it has become established in most subtidal habitats in Port Phillip Bay, Currie *et al.* (2000) suggest that the larger densities on pilings and artificial hard surfaces reflect a preference for settlement on vertical surfaces.

Feeding

Sabella spallanzanii is a filter feeder that traps suspended food particles using its fan-shaped crown of tentacles. It has apparently been reared in the laboratory on a variety of food, but few details of actual diets are available (Parry *et al.* 1996).

Physiological tolerances (range and preferences)

Temperature

Spawning of *S. spallanzanii* occurs when seawater temperatures range between 11°C and 14°C (Giangrande *et al.* 2000). Optimum conditions for growth are at temperatures of between 10-19°C.

Depth

Sabella spallanzanii has been recorded in water depths of 1 m to 30m (Parry *et al.* 1996). In soft sediments, densities tend to be larger at depths of < 7 m, but decline significantly at greater depth (17 to 22 m) (Currie *et al.* 2000). Densities on hard surfaces in Port Phillip Bay generally increased with depth, but were largest between 2 m and 9 m depth (Currie *et al.* 2000).

Salinity

There are few data on the salinity preferences of *S. spallanzanii*. In its native and introduced ranges, it is abundant in sheltered harbours and ports that are subject to fluctuations in salinity, but most studies have been of populations in relatively saline (> 32 psu) waters.

Aquarium weed (*Caulerpa taxifolia*)

General information

Caulerpa taxifolia is a green single-celled alga (Chlorophyta: order Caulerpales, family Caulerpaceae) native throughout many areas of the tropical Pacific and Caribbean (GISP 2002). It is a popular aquarium plant, and prolonged breeding in aquaria and associated exposure to chemicals and UV light are thought to have produced a hardier strain that differs from native plants genetically and has a higher tolerance to cold water temperatures (Jousson *et al.* 1998). *C. taxifolia* has been introduced to at least three geographical regions outside its native range: the Mediterranean Sea on the coasts of Croatia, France, Italy, Monaco, and Spain, (2) the southern Californian coast near San Diego, and (3) parts of the coasts of New South Wales and South Australia (Meinesz 1999; Campbell & Tebo 2001). However, the “aquarium hypothesis” has been challenged by recent work on the temperature tolerance of native populations in eastern Australia (Chisholm *et al.* 2000; see below).

The basic morphology consists of a thallus with horizontal stolons that give off rhizoids and erect feather-like branches, with pinnately arranged pinnules (GISP 2002). In its native range, *C. taxifolia* occurs mostly in small isolated clumps that reach an average height of 25 cm. In the Mediterranean Sea, however, introduced *C. taxifolia* forms dense “astroturf-like” mats with a height of up to three feet, and up to 213 m of stolon growth and 5,000 emerging fronds per square metre (Meinesz 1999; Anderson & Keppner 2001; Yip 2001). *C. taxifolia* produces several types of secondary metabolites (caulerpenyne) that are toxic to potential competitors or grazers belonging to a range of taxa.

Timing of reproduction and recruitment

Little information exists on the reproduction of *C. taxifolia*. Reproduction in native tropical populations can occur sexually during a short period of the year by synchronised (light intensity) release of anisogamous gametes and formation of zygotes (Zuljevic & Antovic 2000). However, Mediterranean and other introduced populations appear to be able to produce only male gametes, and are thus not capable of sexual reproduction. Therefore, reproduction and dispersal of *C. taxifolia* in the introduced range appear to be solely vegetative (asexual) or by fragmentation (Smith & Walters 1999; Anderson & Keppner 2001; Ramey 2001). *C. taxifolia* is pseudoperennial, with highest rates of stolon growth (up to 8 cm day⁻¹) in summer and autumn, followed by a short resting period from January to April (GISP 2002; Neill 2002). Successful recruitment of dispersed fragments of *C. taxifolia* (as small as 10 mm) can occur throughout the year, but establishment probabilities are highest during summer (Ceccerelli & Cinelli 1999).

Habitat and biology

Substratum type

Caulerpa taxifolia occurs on all types of substrata in both native and introduced range. The alga flourishes equally well on rocky, sandy, mud or clay substrata, both in sheltered and exposed conditions, and in polluted and pristine waters (Meinesz *et al.* 1993; Williams & Grosholz 2002). Dense mats of *C. taxifolia* in the Mediterranean smother other benthic biota, including corals, sponges, and other seaweeds (Meinesz 1999; Neill 2002). *C. taxifolia* can adjust its growth strategy to suit the

type of substratum available. For example, in the San Diego population, upright fronds developed adventitious rhizoids and stolons when lying on sediments, and stolons when entwined within existing algal canopy (Williams & Grosholz 2002).

Food preferences

Caulerpa taxifolia occurs in both polluted and nutrient-poor (e.g. the Mediterranean) habitats (Meinesz 1993). The rhizoid system is used to take up major nutrients from the substratum (Anderson & Keppner 2001), and the extensive biomass of *C. taxifolia* mats acts as a vast nutrient trap (P and N) (Yip 2001). Non-native populations of *C. taxifolia* lack severe nutrient (P and N) limitation (Delgado *et al.* 1996), which may be an important factor enabling it to out-compete native macrophytes.

Physiological tolerances (range & preferences)

Temperature

Mediterranean (introduced) populations of *C. taxifolia* have a temperature range of 9 – 32.5 °C. Some reports claim observation of live plants at 5 °C (Makowka 2000). Survival without growth occurs at temperatures of 10 – 12.5 °C; frond and stolon development commence at 15 and 17.5 °C, respectively, with optimum growth occurring at 25 °C (Gillespie *et al.* 1997; Komatsu *et al.* 1997). The lower temperature tolerance limit is thought to occur only in introduced strains, and to have developed during decades of aquarium-breeding. It is common opinion that *C. taxifolia* within the native range do not grow in water colder than 20 °C (Meinesz & Boudouresque 1996). However, recent research from eastern Australia showed that native populations are able to survive temperatures of 11 °C for a period of four weeks, and that a temperature of 13 °C is sufficient to maintain existing tissue biomass (Chisholm *et al.* 2000). Maximum growth occurs at > 20 °C (Komatsu *et al.* 1997).

Depth

Dense mats of *C. taxifolia* commonly occur at depths of 1 – 30 m, but the alga is known to occur down to a depth of ~ 100 m (Meinesz 1999; Anderson & Keppner 2001; Yip 2001). See “Light” (below) for more information.

Salinity

No specific information on *C. taxifolia*'s salinity tolerance range exists in the literature. Populations in the San Diego area were sampled at 34 psu (Williams & Grosholz 2002). Congeners of *C. taxifolia* are able to grow at salinities of 10 – 40 psu (*C. racemosa*; Carruthers *et al.* 1993) and 15 – 50 psu (*C. lentillifera*; Liao & Cheng 1989).

Light

Stolon and frond growth occur at very low light levels (27 $\mu\text{mol m}^{-2} \text{s}^{-1}$); the optimal light intensity ranges from 88 to 338 $\mu\text{mol m}^{-2} \text{s}^{-1}$ (Mediterranean population; no upper irradiation limit established; Komatsu *et al.* 1997). Other studies report highest growth rates at an irradiance of 75 $\mu\text{mol m}^{-2} \text{s}^{-1}$ (Gillespie *et al.* 1997). *C. taxifolia*'s annual productivity pattern is less affected by fluctuations in light and temperature than what has been reported from endemic seaweeds (Gacia *et al.* 1996).

Photosynthetic assays suggest depth limits for colonisation at 80 m (clear water) and 50 m (turbid water) (Gacia *et al.* 1996). Mediterranean *C. taxifolia*'s maximum photoautotrophic growth limit was determined as 24 m during winter. Although this correlates reasonably with the distribution of dense

populations on the Monaco coastline, the limit is greatly inferior to the maximum reported depth of ~ 100 m, and implies significant heterotrophic carbon acquisition at depths much greater than 24 m (Chisholm & Jaubert 1997).

Methods of sampling

There appears to be no single “best” sampling method for *C. taxifolia* due to its occurrence on a range of substrata. Sampling methods that have been used to detect *Caulerpa* and estimate its abundance include visual transects, video transects, quadrat surveys (hard and soft substrata), grab samples (soft bottom) or sled samples (soft bottom).

Clubbed tunicate (*Styela clava*)

General information

The clubbed tunicate, *Styela clava*, is a solitary ascidian native to the northwest Pacific from the Sea of Okhotsk, southern Siberia, Japan, Korea and the coast of China south to Shanghai (Millar 1970, Cohen 2005). It has a club-shaped body, up to 160 mm long, with a distinct stalk and basal disc with which it attaches to the substratum. Small individuals (<30 mm) may lack a stalk (Lützen 1999). The body wall (test) is leathery and variable in colour (commonly brown-white, yellow-brown or red-brown), with conspicuous tubercles on the upper part and longitudinal ridges on the stalk.

Like all ascidians, *Styela clava* is hermaphroditic (but not self-fertile) and gametes are shed into the water column. The “tadpole” larvae peculiar to ascidians are planktonic and hatch from the eggs after ca 12 hr, although the duration of this period varies with egg size and water temperature (Svane & Young 1989, cited in Bourque *et al.* 2005). The larvae are active for a similar period before settling to the substratum (Holmes 1969, cited in Holmes 1976, Minchin *et al.* 2006). The larvae do not feed and at first tend to swim upwards, though this behaviour later reverses (Millar 1970).

In those species of ascidians that have been studied, life-spans are generally 12-20 months, although some may live for several years (Millar 1970). Minchin *et al.* (2006) stated that the size of individual *Styela clava* (75-180 mm) collected in Ireland “suggests that they were between one and two years old”, although they did not give any reason for this conclusion. Individuals that settled in the Limfjord, Denmark in mid-August grew to 17-48mm by the end of October (Lützen 1999), after which growth ceased during the colder months. Considerable mortality of smaller individuals also occurred during winter. Survivors reached lengths of 50-75 mm by June and became fully mature, spawning in July and August at 75-95 mm. Many small (12-40-mm-long) individuals were also present in early and mid-summer, representing late settlers from the previous year. These, and some of the larger individuals, probably survive a second winter to reach a length of 110-120 mm and reproduce for a second time aged 1.75-2 years old. The lifespan of individuals in southern England was found to be shorter, only rarely exceeding 15 months (Holmes 1969, cited in Lützen 1999). Death may result from senescence, predation or adverse environmental conditions. Reported predators of juvenile *Styela clava* include gastropods (*Mitrella lunata* in eastern North America) and fish (NIMPIS 2002).

The first recorded occurrences of *Styela clava* outside its native range were at Newport Bay (1932) and Elkhorn Slough (1935, a single specimen and no longer present at this site), both in California (Cohen 2005). It subsequently spread along the Pacific coast of North America, north as far as Puget Sound (collected in 1998) and Vancouver Island (collected in 1994) and south as far as Baja California (collected at Ensenada in 2000). On the east coast of North America, it was collected in Massachusetts in 1970, New York in 1972, Connecticut, Maine, New Hampshire and Rhode Island in the 1980s and, more recently, in New Brunswick and Prince Edward Island (1998) (Cohen 2005).

Styela clava was recorded in southwest England in 1953 (Carlisle 1954, Houghton & Millar 1960, both cited in Eno *et al.* 1997) and has since spread to northwest England, southwest Scotland and southern Ireland (collected 1972: Minchin & Duggan 1988). It has also been found in France (1968),

the Netherlands (1974), Denmark (1978-1979), Germany (1997), Portugal (2003) and Spain (2004) (Lützen 1999, Cohen 2005, Davis & Davis 2005).

The first record of *Styela clava* in Australia was in 1972 in Port Phillip Bay, Victoria (Holmes 1976) and in 1977 it was reported from Sydney Harbour, New South Wales (Cohen 2005). It was first recorded in New Zealand in the Viaduct Harbour, Auckland in August 2005 and there appear to be well-established populations in the Waitemata Harbour, Hauraki Gulf and Firth of Thames (Gust *et al.* 2006a). More localised populations have also been found in Lyttelton Port, Lyttelton Marina, Tutukaka and Opuia Marinas (Northland) (Gust *et al.* 2006a and b) and Nelson Port (Morrisey *et al.* 2006).

Timing of reproduction and recruitment

Reproduction is usually restricted to warmer seasons in ascidians living in temperate and cold seas (Millar 1970). Holmes (1969, cited in Holmes 1976) reported that *Styela clava* bred throughout all but the coldest 2-3 months in southern England, with a marked peak of settlement in mid-late summer (late July-early September). A similar pattern of settlement was observed in the Limfjord, Denmark (Lützen & Sørensen 1993, cited in Lützen 1999). Monthly sampling of *S. clava* in southern Ireland (Parker *et al.* 1999) showed gametogenesis (presence of ripe gametes in the gonads) from February-November, with a peak in August-October, and spawning in September-October (when average water temperatures were 15.2°C (±0.4 SD) – 14.1°C (±1.3 SD)).

Spawning in ascidians generally occurs in response to a period of light following a period of darkness (Svane & Young 1989, cited in Bourque *et al.* 2005). The rapidity of response to this period of light varies among species and, therefore, not all species spawn at the same time of day. Time of spawning may also vary among populations of the same species from different locations (Bourque *et al.* 2005). In *Styela plicata*, the duration of the light period required to stimulate spawning decreases with increase in the preceding period of darkness (West & Lambert 1976, cited in Bourque *et al.* 2005). Light intensity may also affect the duration of the light period prior to spawning (Forward *et al.* 2000, cited in Bourque *et al.* 2005). Bourque *et al.* (2005) found that concentrations of larvae of *Styela clava* in the upper 1-m of the water column at a field location in Prince Edward Island, eastern Canada, peaked around noon. They pointed out, however, that timing of peak concentrations of larvae may vary among locations and over time at the same location, in response to factors such as day-length, water temperature and light intensity. Cohen 2005 and ISSG Global Invasive Species Database 2006 indicate that *Styela clava* is only able to spawn at water temperatures above 15°C and salinities above 25-26 psu (no sources are given for this information).

Larvae of *Styela clava* do not usually travel more than a few centimetres by active swimming (Minchin *et al.* 2006). Consequently they tend to congregate close to the parent population, although they can be passively dispersed over distances covered by 1-2 tidal excursions (equivalent to the duration of the larval period). Larvae are negatively buoyant but negatively geotactic and positively phototactic, particular at higher hydrostatic pressures, and consequently tend to settle near the water surface (Davis 1997, cited in Minchin *et al.* 2006). Suitable conditions for establishment occur in sheltered localities with salinities of >22 psu and temperatures ≥16°C for several weeks (Minchin *et al.* 2006). Individuals apparently reach maturity at 3-10 months (Cohen 2005).

Habitat and biology

Styela clava occurs in low wave-energy environments and sheltered embayments from the upper sublittoral zone to at least 25 m depth (ISSG Global Invasive Species Database 2006). It is especially abundant 10-200 cm below the sea surface (Lützen 1999), and the fact that it has been recorded up to 30 cm above the level of extreme low water of spring tides in southern England (Holmes & Coughlan 1975, cited by Lützen 1999) suggests that it is able to withstand a degree of regular exposure to air. It can apparently survive for up to 3 days out of water under cool, damp conditions (Lützen & Sørensen 1993, cited in Minchin *et al.* 2006). Based on a survey of the distribution of *S. clava* in harbours of the Southern Californian Bight, Lambert & Lambert (2003) noted that the species was consistently more abundant closer to the entrances to bays, where water currents were stronger and that it differed from *S. plicata* in this respect.

Substratum type

Natural substrata for attachment of *Styela clava* include rocks, the blades of macroalgae and the shells of live and dead bivalves (Lützen 1999, NIMPIS 2002, Bourque *et al.* 2005). *S. clava* is also found on a range of artificial structures, including floating pontoons, tyre fenders, vessels, buoys and anchors, and diverse materials, including concrete, cement, wood, ropes and the steel or fibreglass hulls of vessel (Bourque *et al.* 2005, Gust *et al.* 2005, 2006a, ISSG Global Invasive Species Database 2006, Minchin *et al.* 2006). In a survey of harbours in southern California, Fay & Johnston (1971, cited in Lambert & Lambert 2003) recorded *Styela clava* only on floats and pilings and not on any natural substrata.

According to Holmes (1976), *Styela clava* colonises only those surfaces bearing a well-developed epibiota. It can attach to larger individuals of its own species and individual *S. clava* may be extensively fouled with smaller tunicates of their own or other species, algae, sponges, hydroids and bryozoans (Lützen 1999, Cohen 2005, Minchin *et al.* 2006).

On natural substrata, such as rocks or bivalve shells, *Styela clava* is reported to reach population densities of 50-100 m⁻² (Lützen 1999). On artificial substrata, however, much higher densities have been reported (500-1500 m⁻²: Holmes 1976, NIMPIS 2002).

In New Zealand *Styela clava* has been found attached to floating pontoons, wooden pier piles, suspended mooring lines and vessel hulls (Gust *et al.* 2006a). It has also been reported attached to dead bivalve shells on a muddy shore in the Tamaki Estuary, Auckland (Chris Hickey, NIWA, pers. comm.).

Food preferences

Styela clava is a suspension feeder, feeding on suspended, particulate matter, such as phytoplankton, zooplankton and organic detritus, filtered from water pumped through its branchial sac.

Physiological tolerances (range and preferences)

Temperature

Styela clava is reportedly able to tolerate temperatures ranging from –2 to 23°C (Minchin *et al.* 2006). Holmes (1969, cited in Holmes 1976) described a population living in southern England, where water temperature ranged from 2-23°C, and breeding in all but the coldest 2-3 months of the year. On the Pacific coast of North America it has been found at water temperatures ranging from 11-27°C (Cohen 2005). Larvae are able to survive temperatures from 10 - 30°C (Boothroyd *et al.* 2003).

Parker *et al.* (1999) reported no evidence of gametogenesis in individuals sampled in early February in southern Ireland, when the water temperature was 3-4°C, but small numbers of ripe gametes in individuals sampled in the middle of the same month, when the temperature had risen to 8°C. There was evidence that gonad maturation occurred at temperatures below 8°C. Gametogenesis and spawning peaked in August-October, when water temperatures ranged from 14-18°C.

Depth

The reported depth range for *Styela clava* ranges from just above the level of extreme low water of spring tides (in southern England: Holmes & Coughlan 1975, cited by Lützen 1999) to at least 25 m (NIMPIS 2002). Lützen (1999) described *S. clava* as a “predominantly littoral species, which is especially abundant 10-200 cm below the sea surface in areas without tides or when attached to floating objects....The species may extend to depths of 15-25 m...but a record of 40 m depth...is probably exceptional”.

Salinity

Styela clava appears to avoid areas with estuarine conditions (Lützen 1999). Sims (1984, cited in Lützen 1999) found that Californian specimens showed poor vital functions after 3-d immersion in 26.5 psu seawater. This corresponds with Lambert & Lambert's (2003) observation of die-offs of *S. clava* on floating structures in southern California after heavy rain (followed by rapid recolonisation). They also cited an earlier study (MacGinitie 1939) in the same area that found complete mortality of *S. clava* below a sharp halocline that formed at a depth of ca 2.2 m following heavy rain. Below this depth there was no evidence of any mortality. Individuals can, however, survive shorter periods of salinity as low as 8 psu, presumably by closing their siphons (Sims 1984, cited in Lützen 1999).

Other populations of *Styela clava* may be more tolerant of lower salinities than those studied in California. In the eastern Limfjord (Denmark), populations exist in salinities averaging 26-28 psu, with decreases to <20 psu for periods of several days (Lützen 1999). Individuals experimentally exposed to stepwise decreases in salinity from 31-18 psu showed >50% survival for 40 d (at 12°C) and 50% survival when the salinity was further reduced to 16 psu (Lützen & Sørensen 1993, cited in Lützen 1999). Lützen (1999) cited a report that larvae of *S. clava* from the Sea of Japan were able to complete metamorphosis at salinities of 20-32 psu, but that <18 psu was “deleterious” (no definition given). Cohen (2005) stated that adult *S. clava* die in salinities <10 psu, but did not give a source for this information.

In summary, salinity tolerance of adults and larvae appears to extend as low as 18 psu for extended periods (and much lower for short periods), but may be dependent on the salinity regime to which the population has previously been exposed.

Route of introduction

Styela clava may have reached the Pacific coast of North America as fouling on ships' hulls, but it may also have been introduced as fouling on imported live oysters (Cohen 2005). It is known to occur on oysters (*Crassostrea gigas*) in Japanese oyster farms, and oysters from Japanese farms were transplanted to Elkhorn Slough (California) in 1929-1934, roughly coincident with its date of first detection in California (1932). From Elkhorn Slough it could have been transported to other parts of California as fouling on coastal shipping or via further transfer of oyster stock (including its recent appearance in Humboldt Bay: Cohen 2005).

The introduction of *Styela clava* to southern England is commonly ascribed to fouling on naval vessels returning from the Korean War in 1952 (Minchin & Duggan 1988, cited in Minchin *et al.* 2006), having acquired fouling in the Yellow Sea. It is likely to have spread from the original site of introduction to other parts of the United Kingdom and continental Europe on coastal shipping or, locally, by dispersal of eggs and larvae (Lützen 1999). It has also been suggested that *S. clava* reached the Danish coast, where it was first recorded on an oyster bed in the Limfjord, attached to oysters imported from the English Channel and re-laid in the Limfjord (Lützen 1999). Oyster spat imported from Japan in the 1970s, or transplanted within the English Channel region, may have contributed to the establishment of Dutch and French populations (Lützen 1999).

Given the distances involved, the introduction of *Styela clava* to Australia and New Zealand is likely to have occurred via fouling on ships' hulls, either from its native range or from introduced populations in Europe or North America. In view of the disjunct distribution of *S. clava* in New Zealand's North and South Islands, several inoculation events may have occurred (Gust *et al.* 2006a). Research is currently underway to determine the genetic relationships among populations of *S. clava* in New Zealand.

Minchin *et al.* (2006) noted that *S. clava* tend to be stripped from ships' hulls at speeds above ca 5 kt, unless they occur in more protected habitats such as sea-chests, thruster tubes, or in the lee of stabilisers and other structures on the hull. Lützen (1999) also described *S. clava* as rheophobic (i.e. avoiding strong currents), reducing the likelihood of individuals surviving as fouling on exposed parts of the hulls of rapid vessels in continuous service. Attachment to drifting macroalgae provides another potential means of dispersal. Lützen (1999) stated that fronds of *Sargassum muticum* (a macroalga introduced to Europe from Asia in the early 1970s) with *Styela clava* attached are often washed up on shores in the Limfjord. Fronds become detached from their holdfasts towards the end of the growth cycle and can float for "considerable distances".

Davis & Davis (2004) suggested that a combination of transport mechanisms, including translocation on oyster shell, dispersal on flotsam such as drift macroalgae, fouling on vessel hulls, transport of eggs and larvae in ballast water, and fouling of sea-chests are probably required to explain the present distribution of *S. clava*. Davis (2005) suggested that sea-chests were potentially of greatest importance

because they offer a means of transport for established colonies of individuals, and translocated colonies are more likely to establish new populations than a single inoculum of larvae.

Slow-moving and towed vessels are particularly likely mechanisms of introduction, because of the reduced likelihood of individuals being removed from the hull by water currents during transit. Such vessels may also spend longer periods moored in ports of origin and destination than vessels in continuous service. Specimens of *S. clava* found on vessels in New Zealand have been on a tug (Lyttelton), recreational launches and yachts (Auckland, including one that subsequently travelled to Waikawa Marina, Picton, where it was found to harbour a single individual) and fishing vessels (Nelson) that had been berthed for long periods of time (possibly months in one case, years in another). Of these, recreational vessels are perhaps the most likely to have been the vector of inoculation in the ports where they were found, as the other types of vessel tend to spend most of their time in their home port.

Methods of sampling

- Lambert & Lambert (2003) sampled harbours by examining the sides and bottom edges of pontoons and vessels in marinas, manually removing clumps of fouling organisms to arms' depth, and recovering 5-m long ropes deployed 4 years previously.
- Minchin *et al.* (2006) sampled floating pontoons, supporting piles and quay walls by feeling for specimens by hand, or by scraping adhered biota from the surfaces.
- Gust *et al.* (2005, 2006a,b) employed above-water searches from shore or boat to detect *S. clava* on pontoons, pilings, breakwalls, buoys, heavily-fouled vessels and mooring lines. Submerged ropes were pulled up and examined. Selection of vessels to search was based on a risk-profiling approach based on empirical relationships between level of fouling and probability that the fouling assemblage includes solitary ascidians.
- Gust *et al.* (2005, 2006a,b) also used in-water diver searches of the undersides of pontoons, wharf piles and breakwalls. For safety reasons, and because previous studies had shown that 70% of all *S. clava* detected were found within this depth, searches were confined to the upper 5 m of the water column.
- The probability of *S. clava* being detected by searchers when it is present can be estimated for each type of substratum in a given harbour. These estimates require information on the proportion of the total area of the substrate searched and the sensitivity of the search method under prevailing environmental conditions, particularly water clarity (Gust *et al.* 2006a,b). Sensitivity, the ability of the searchers to detect *S. clava* when present, can be determined by searches for experimentally-deployed mimics of the organism. Details of the methods are given in Gust *et al.* (2006a,b).
